# Early Bill-of-Quantities estimation of concrete road bridges:

## *An artificial intelligence-based application*

### Abstract

Accurate cost estimation in the preliminary stages of project development is critical for making informed planning decisions. However, such early estimates are typically restricted by limited information. In this paper, the widely recognised intelligence of Feed-Forward Artificial Neural Networks (FFANNs) is used to process actual data from 68 concrete road bridges and provide a surrogate model for the accurate estimation of the Bill-of-Quantities (BoQ). Specifically, two FFANNs are trained to estimate the superstructure and piers concrete and steelbased on the construction method and the bridge dimensions. As the relevant metrics demonstrate, the FFANNs capture very well the complex interrelations in the dataset and produce highly accurate estimates. Furthermore, their generalization capability is superior to the capability ofrespective linear regression models. As the data used to train the FFANNs is normally available early in the project lifecycle, the proposed model enables early, yet accurate cost estimates to be obtained.

## Introduction

Providing accurate forecasts of construction costs in the preplanning phases of construction projects is vital (Dursun & Stoy, 2016) as cost estimation accuracy has decisive impact on strategies for asset development, potential project screening, and resource commitment for further project development (Oberlender & Trost, 2001). Estimates prepared at the initial stages of a project can play several important roles: they can form the basis of cost-benefit analysis, for selection of potential delivery partners, to support a to-build-or-not-to-build decision, and very often as a benchmark for future performance measure (Ahiaga-Dagbui & Smith, 2014). They are also typically used for the estimation of preconstruction costs as a fixed or sliding percentage (Hollar & Rasdorf, 2013).

The soaring urban and inter-urban traffic needs generate an ever-increasing pressure for allocation of funding towards the construction of motorway infrastructure. This is a critical issue which currently attracts significant debate and disagreement (Hollar et al., 2013). Gibson, Denison, Wallace and Kreis (2015) note that the fiscal developments of recent years make it difficult to plan appropriate policies and infrastructure projects that maintain transportation systems at current service levels as the available public funding does not necessarily meet the expanding transportation needs of citizens. In this context, as motorway projects require a substantial investment of funds, developing a reliable and accurate project cost estimate in the initial decision-making process is a task of critical importance to the sponsoring organisation and the project team.

Apparently, in times of resource scarcity, it is even more necessary for the decision makers to estimate the budget of high-cost, large-scale construction projects like road bridges with adequate accuracy, early in the planning process, in order for the national funds to be invested as

1  
2  
3 efficiently as possible. However, the required accuracy is notoriously difficult to be achieved as  
4  
5 the conceptual stage involves very limited project information. Yeung and Skitmore (2012) note  
6  
7 that in the very early stages of construction projects, there are situations where only such basic  
8  
9 information as project type, project size and preliminary project specification is known  
10  
11 concerning a new project and the client-owners' consultant estimators have to resort to using  
12  
13 either the price of a very similar project or the mean price of a (base) group of projects. Similarly,  
14  
15 Hyari, Al-Daraiseh and El-Mashaleh (2016) highlight the fact that detailed estimates are usually  
16  
17 possible not earlier than the stage of procurement, i.e. after completion of the detailed project  
18  
19 design and therefore, earlier cost estimates can only be based on historical data and cost  
20  
21 forecasting models. This unsurprisingly leads to early estimates being highly inaccurate with the  
22  
23 final actual cost exceeding in the vast majority of cases the initial estimate.  
24  
25  
26  
27  
28  
29

30 As Rosenfeld (2014) notes, cost overruns in construction are a worldwide phenomenon  
31  
32 with no geographical limits nor cultural associations. Flyvbjerg, Holm and Buhl (2003) highlight  
33  
34 the correlation between cost overruns and project size arguing that larger projects present higher  
35  
36 percentage cost escalations while other factors such as premature tender documents (Rosenfeld  
37  
38 2014) and procurement choices (Chen et al. 2016) have also been strongly associated with this  
39  
40 global problem. Especially in the field of transportation projects, Flyvbjerg, Holm and Buhl  
41  
42 (2003) note that the magnitude of cost overruns in highway projects and motorway bridges is  
43  
44 substantially high. Specifically, nine out of ten transport infrastructure projects fall victim to cost  
45  
46 escalation, which for fixed links (tunnels and bridges) and roads has an average value of 34% and  
47  
48 20% respectively. Furthermore, Lee's (2008) analysis of roads, rails, airports and ports projects  
49  
50 found that road and rail projects had a maximum cost overrun of 50%. Vidalis and Najafi (2002)  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 in their research on 708 highway projects for the Florida Department of Transportation found a  
4  
5 combined cost overrun of \$200 million.  
6  
7

8 This research paper introduces an Artificial Neural Network (ANN)-based model which,  
9  
10 utilising actual Bill of Quantities (BoQ) data from 68 road bridge projects, enables the reliable  
11  
12 estimation of the bridge superstructure and piers material quantities and by extension the more  
13  
14 accurate estimation of the relevant cost. This is achieved by multiplying the quantities predicted  
15  
16 by the model with the unit prices specified by the user. The use of material quantities as a means  
17  
18 to extract the cost instead of developing a model to directly predict the cost, enhances the  
19  
20 reliability of the estimation process. This results from the fact that the BoQ is based on final  
21  
22 designs compliant to international standards with wide acceptance and use across countries (e.g.  
23  
24 DIN, Eurocodes, AASHTO) while on the contrary, cost values are heavily influenced by country-  
25  
26 specific actors (e.g. tendering system, inflation rate) which need to be adjusted for the model to  
27  
28 be used more widely.

### 34 35 **Literature Review**

#### 36 37 **Research in road bridge cost analysis and management**

38  
39 The analysis of the construction cost of concrete bridges has been the aim for numerous  
40  
41 past research efforts. Menn (1990) used a small sample of 19 motorway bridges built in  
42  
43 Switzerland between 1958 and 1985 to investigate the cost of prestressed concrete bridges. He  
44  
45 broke down the bridge structure into four components, i.e. mobilization, substructure,  
46  
47 superstructure, and accessories and concluded that these factors' contribution to the total bridge  
48  
49 construction cost is 8.00%, 23.50%, 54.50%, and 14.00%, respectively. Fragkakis and  
50  
51 Lambropoulos (2004) collected actual cost information from a large sample of 119 concrete  
52  
53 bridges and overpasses constructed between 1999 and 2003 as part of the Egnatia Motorway in  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Greece. They divided the actual bridge construction cost into earthworks, foundation,  
4  
5 substructure, superstructure and accessories and proposed the average cost values for four major  
6  
7 deck construction methods. For example, concerning bridges consisting of precast prestressed  
8  
9 beams and reinforced concrete slabs, the average cost percentages for the five elements above are  
10  
11 4.70, 26.70, 15.90, 34.40 and 18.30 % respectively.  
12  
13  
14

15 The review of publications relating to cost estimation for road bridges reveals that very few  
16  
17 studies use actual as-built design and structural data in order to produce cost estimate models.  
18  
19 Fragkakis, Lambropoulos and Tsiambaos (2011) developed a bridge database with complete data  
20  
21 from 157 pier foundations and developed a parametric model for conceptual cost estimation of  
22  
23 concrete bridge foundations. A database with design and structural data for 322 bridge piers was  
24  
25 used from Fragkakis, Lambropoulos and Pantouvakis (2014) in order to develop a cost estimate  
26  
27 model for piers with regression analysis. Furthermore, Fragkakis, Lambropoulos and Pantouvakis  
28  
29 (2010) applied regression analysis on a database consisting of 68 structures and derived material  
30  
31 estimating models for three widely used deck construction methods (cantilever construction,  
32  
33 precast pre-stressed beams, cast-in-situ box girders). Bridge cost estimation guidelines, mostly  
34  
35 based on historical bid data, have also been developed by Departments of Transportation (DoT)  
36  
37 in U.S. Such examples are California (2011), New York (2016) and Florida (2017). Moreover, in  
38  
39 Dimitriou and Charmpis (2015) and Charmpis and Dimitriou (2015) alternative optimisation  
40  
41 formulations and algorithmic configurations have been tested on a realistic large-scale sample of  
42  
43 nearly 15,000 bridges from NY, USA, exposing the gains of optimal selection mechanisms on  
44  
45 budget utilisation, while highlighting the importance of accuracy in bridges rehabilitation cost  
46  
47 appraisal.

Most efforts on cost estimation of concrete bridges are constrained by design standards and codes and are based on a trial-and-error computer-aided process aiming to optimise the design from a technical or economical viewpoint. Sirca and Adeli (2005) addressed precast, prestressed concrete bridge systems consisting of type I beams and developed an optimization method for the superstructure cost. The general design process of the superstructure and the standard cross sections were based on the AASHTO specifications. The model addressed the superstructure as a single system and did not explore the superstructure components. Cohn and Lounis (1994) explored the optimal design of concrete motorway bridges through a three-level cost optimization approach. Their research concentrated only on the superstructure of prestressed bridges with span length between 10.00 and 15.00 m. and deck width between 8.00 and 16.00 m. They addressed superstructure systems with solid or voided slabs, single-cell box girders and precast prestressed beams with reinforced concrete composite slab. Lounis and Cohn (1993) proposed a method for bridges consisting of precast prestressed girders with reinforced concrete slab that enables the selection of the most economical girder type, optimal girder spacing, optimal prestressing force, and minimum superstructure cost per unit deck area. The specifications and constraints of the Ontario Bridge design standard were used. Aparicio, Casas and Ramos (1996) proposed a computer-aided design and cost estimating system addressing all elements of concrete highway bridges. The software package represents an expert system that uses specific design constraints to perform the complete bridge design. It produces the geometry and cost of all bridge elements and extracts design drawings. A thorough review of publications on cost optimisation of concrete bridge components and systems has been presented by Sarma and Adeli (1998) and Hassanain and Loov (2003). The aforementioned studies address only the bridge superstructure and use standard beam shapes and cross sections dictated by the American or Canadian design standards

1  
2  
3 and specifications. The research is characterized by the computer-intensive theoretical resolutions  
4  
5 that result in the optimization of the final design from both technical and economic viewpoints.  
6  
7 Although cost estimates based on computer-aided resolutions provide helpful insights, they fail to  
8  
9 address the designers' attitude and experience that influence the as-built structural quantities for  
10  
11 each project, as well as the structural changes that take place during the project's construction  
12  
13 and were not predicted during the design phases.  
14  
15

### 16 17 18 **Cost prediction at early design stages: challenges and methodological approaches** 19

20  
21 According to Burke (1999) and Flyvbjerg, Holm and Buhl (2002), at each phase in the  
22  
23 project implementation (conception, tendering, design, construction) different levels of cost-  
24  
25 estimating accuracy can be achieved from the detail of information available. Specifically the  
26  
27 early cost estimates made at the conception phase are based on designs which only correspond to  
28  
29 a general idea about what the project will entail, at a completion level of about 30%. As a result,  
30  
31 many of the costs must be inferred from costs associated with past projects (Asmar, Hanna,  
32  
33 &Whited, 2011). Nicholas (2004) also refers to the lack of realistic and accurate estimates as a  
34  
35 result of inadequate information and highlights the fact that estimators have to rely largely on  
36  
37 their own experience and historical cost information when preparing initial estimates. Ahiaga-  
38  
39 Dagbui and Smith (2013) observe that an estimate can only be as good as the information it is  
40  
41 based on so that, *ceteris paribus*, the level of accuracy of the estimates produced also increases as  
42  
43 more information becomes available. However, despite their low level of accuracy, early cost  
44  
45 estimates are used as the basis for the comparative evaluation of different investments decisions,  
46  
47 design alternatives and eventually the selection of the most efficient technical solution. Odeck  
48  
49 (2004) discusses the risk of inefficient investment decisions resulting from unreliable early cost  
50  
51 estimations. He particularly highlights the fact that underestimated costs may be deceptive  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 as when the viability of the project is being evaluated, the decision maker probably makes  
4  
5 decisions based on larger values of Net Present Value than the actual ones. The end result may be  
6  
7 that non-viable projects are being implemented and resources are inefficiently allocated due to  
8  
9 inaccurate estimates.  
10

11  
12 In this context, the uncertainty which is inherent in the pre-construction phase of projects  
13  
14 has repeatedly been connected by the literature with the occurrence of cost overruns. Flyvbjerg,  
15  
16 Holm and Buhl (2002) note that the likelihood of actual costs being larger than estimated at a  
17  
18 randomly selected project reaches the impressive percentage of 86%. Durdyev, Ismail and Bakar  
19  
20 (2012) in their research for residential projects identified improper planning and inaccurate  
21  
22 project cost estimation among the factors affecting cost overruns. Similarly, in their analysis for  
23  
24 infrastructure projects, Lee (2008) examined 161 roads, rails, airports, and ports projects and  
25  
26 concluded changes in the scope and unreasonable cost estimation have substantial impact on cost  
27  
28 overruns. Similar conclusions for the impact of inaccurate cost estimates were also presented by  
29  
30 Le-Hoai, Lee and Lee (2008). Cantarelli, vanWee, Molin and Flyvbjerg (2012) also note that  
31  
32 road projects are particularly vulnerable to exceeding the estimated costs in the pre-construction  
33  
34 phase and argue that although this phase is significantly shorter than the construction phase, it has  
35  
36 the highest influence on cost overruns. Bridge construction in particular also presents substantial  
37  
38 budget overruns (Odeck, 2004; Flyvbjerg, Skamris, & Buhl 2004, 2007; Azhar, Farooqui, &  
39  
40 Ahmed, 2008).  
41  
42  
43  
44  
45  
46  
47

48 Numerous models have been developed to support decision makers in the challenging task  
49  
50 of estimating construction project cost. Among the most popular and well-established modelling  
51  
52 techniques for this purpose are the ANNs. An ANN is an information-processing system that has  
53  
54 been developed as a generalization of mathematical models of human cognition or neural biology  
55  
56  
57  
58  
59  
60

1  
2  
3 and exhibits the ability to capture the nonlinear relationships between variables. ANNs are made  
4  
5 of simple processing units, called neurons, capable of storing experimental knowledge as a  
6  
7 natural propensity. The elementary backpropagation artificial neuron forms the base component  
8  
9 of the ANN. Typically the neuron is configured with a number of inputs, with each input having  
10  
11 an associated weight which multiplies the signal transmitted. An activation/transfer, often sigmoid  
12  
13 function is applied to convert the input of each neuron to  
14  
15 output. The ANN type most suited for developing predictive models is the Feed-Forward ANN  
16  
17 (FFANN) trained using a back-propagation algorithm that uses a gradient-descent approach for  
18  
19 adjusting the ANN weights (Attalla & Hegazy, 2003). Back-propagation ANNs consist of an  
20  
21 input layer, an output layer, and one or more hidden layers. The number of layers and the  
22  
23 numbers of neurons in each layer determine the capability of the network to figure out the  
24  
25 relationship between the independent variables and the dependent one. A single hidden layer is  
26  
27 sufficient for almost any problem (Setyawati, Sahirman, & Creese, 2002). An ANN is  
28  
29 feedforward if there exists a method which numbers all the nodes in the network such that there is  
30  
31 no connection from a node with a large number to a node with a smaller number. All the  
32  
33 connections are from nodes with small numbers to nodes with larger numbers (Yao, 1999).  
34  
35  
36  
37  
38  
39

40 The ANN gains its problem-solving capabilities through generalization of the knowledge gained  
41  
42 during its training. According to Zhang, Patuwo and Hu (1998) the training process is usually as  
43  
44 follows. First, examples of the training set are entered into the input nodes. The activation values  
45  
46 of the input nodes are weighted and accumulated at each node in the first hidden layer. The total  
47  
48 is then transformed by an activation function into the node's activation value. It in turn becomes  
49  
50 an input into the nodes in the next layer, until eventually the output activation values are found.  
51  
52 The training algorithm is used to find the weights that minimize some overall error measure such  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 as the sum of squared errors (SSE) or mean squared errors (MSE). Hence the network training is  
4  
5 actually an unconstrained nonlinear minimization problem. When supervised training is applied,  
6  
7 input and output parameters of training data are randomly presented to the network thousands of  
8  
9 times, called cycles or epochs. In each epoch, the network applies its training algorithm and  
10  
11 calculates its predicted output. The errors between the predicted and the actual outputs are  
12  
13 propagated backward to adjust the network's weighted connections so that the predicted output  
14  
15 matches or becomes as close as possible to the actual output. This process is mathematically  
16  
17 guaranteed to converge (Rumelhart, Hinton, & Williams, 1986). The distinct advantage of ANNs  
18  
19 over the nonlinear regression is that no exact knowledge of the nonlinear relationship between the  
20  
21 input and output variables is required as these relationships are determined implicitly by the ANN  
22  
23 and therefore do not need to be specified by the user. The error of the trained model is used as a  
24  
25 metric of its generalization capability. As Svozil, Kvasnicka, & Pospichal (1997) explain, a  
26  
27 network generalises well when the input-output relationship computed by network is correct (or  
28  
29 nearly correct) for input/output patterns never used in training the network. When the learning  
30  
31 process is repeated too many times, then, overfitting may occur due to the network memorising  
32  
33 the training data instead of capturing the underlying correlations among variables. In such case,  
34  
35 the network performs satisfactorily during the training process but fails with data from the test  
36  
37 set. Thus, the network has reduced generalization capability. The most commonly used method  
38  
39 for avoiding overfitting is early stopping. This involves dividing data into two sets, one for  
40  
41 training and one for validation, and computing the validation error periodically during training.  
42  
43 Training stops when the validation error rate starts to increase. However, the validation error is  
44  
45 not a good estimate of the generalization error, and thus, a third set of data, not used during the  
46  
47  
48  
49  
50  
51

2  
3 training process, is necessary to check the generalization performance of the ANN. This third set  
4  
5 is called test set.  
6  
7

8 ANNs' powerful capabilities for capturing and modelling complex interrelations in real-  
9 world datasets have been widely identified in the literature (e.g. Marinelli, Lambropoulos,  
10 & Petroutsatou, 2014; Dimitriou & Hassan, 2013; Karlaftis & Vlahogianni, 2011; Moselhi,  
11 Hegazy, & Fazio, 1992) and their suitability for cost estimation of different kinds of construction  
12 projects like buildings (Gunaydin & Dogan, 2004; Kim, An, & Kang, 2004), tunnels  
13 (Petroutsatou, Georgopoulos, Lambropoulos, & Pantouvakis, 2012), highway projects (Hegazy &  
14 Ayed, 1998; Al-Tabtabai, Alex, & Tantash, 1999; Xin-Zheng, Xiao-Chen, & Jing-Yan, 2010),  
15 drainage projects (Alex, Al Hussein, Bouferguene, & Fernando, 2010), water projects (Shehab,  
16 Farooq, Sandhu, Nguyen, & Nasr 2010, Chau & Sethi, 2012), hydroelectric power plant projects  
17 (Gunduz & Sahin, 2015) has also been highlighted. Other applications of ANNs include financial  
18 tools, electric load consumption prediction and intelligent manufacturing systems (Huang &  
19 Zhang 1994, Zhang, Patuwo & Hu (1998). Frazer (1995) also investigates the use of computer  
20 based techniques and models in the field of architecture.

41 In the area of bridges, Creese and Li (1995) used data from 12 timber bridges to develop an  
42 ANN capable for the estimation of the bridge cost from the volume of webs, the volume of the  
43 bridge decks and the weight of steel. Similarly, Ugwu and Kumaraswamy (2004) used data of  
44 location, pavement material and project configuration from 74 highway bridges in Hong Kong to  
45 train an ANN to predict their construction cost. Furthermore, Morcous, Bakhom, Taha, & El-  
46 Said (2001) used data from 22 pre-stressed concrete bridges constructed in Egypt to develop a  
47 ANN capable of estimating the concrete volume and pre-stressed steel weight of bridge  
48 superstructures. The input attributes selected for the training of the ANN model were: the  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 maximum span length, the superstructure type, the structure system, the construction method, the  
4 contract type, and the design type. Testing results with cross-validation experiments resulted in  
5  
6 average network errors smaller than 11.50% in both output variables.  
7  
8  
9

10  
11 The literature survey indicates that ANNs have been used efficiently for the preliminary  
12 quantity estimate of highway bridges despite the difficulties emerging from the use of different  
13 design codes as well as the reluctance of public clients to supply financial information regarding  
14 constructed projects. Other methods frequently employed for project cost estimation include  
15 regression analysis (e.g. Trost & Oberlender, 2003; Lowe, Emsley, & Harding, 2006; Wang &  
16 Horner, 2007; Fragkakis, Lambropoulos, & Pantouvakis, 2010; Jafarzadeh, Wilkinson, González,  
17 Ingham, & Ghodrati Amiri 2014) and case-based reasoning (e.g. Karshenas & Tse, 2002; Kim &  
18 Kang, 2004; Doğan, Arditi, & Gunaydin, 2008; Koo, Hong, Hyun, & Koo, 2010). Kim, An, &  
19 Kang (2004) provide comparison of all the 3 methods performance and advantages /  
20 disadvantages. Their research based on the analysis of actual construction costs of 530 projects of  
21 residential buildings, concluded that the best ANN model performed more effectively than the  
22 other two approaches in estimating construction costs. Quite a number of other researchers have  
23 also verified the performance superiority of ANNs over regression. For instance, Attalla and  
24 Hegazy (2003) compared the two methods' performance in reconstruction cost prediction and  
25 concluded that the ANN-based model was able to include a much greater number of variables.  
26 Similarly, Shehab, Farooq, Sandhu, Nguyen and Nasr (2010) concluded that the ANN developed  
27 for water projects cost prediction produced much more accurate results compared to the  
28 regression one and thus demonstrated superior capabilities in mapping relationships between  
29 inputs and outputs in limited data environments. Gunduz and Sahin (2015) also confirmed in  
30 their research that the ANN that was trained on cost data from forty one hydroelectric power

### 10 11 **Development of FFANN-based model for Road Bridge BoQ estimation**

#### 12 13 **Data collection**

14  
15  
16  
17 The data used for the development of the model were collected from the final BoQs of 68  
18  
19 bridges of Egnatia Motorway, a 680-km-long motorway constructed in northern Greece between  
20  
21 1996 and 2008 as part of the trans-European Transport Network. The whole project includes 646  
22  
23 concrete bridges which account for the 20% of the total construction cost. The greatest overall  
24  
25 bridge length exceeds 1,000 m, and the longest single span reaches at 235 m. The designs were  
26  
27 carried out by Greek and international structural design firms following international  
28  
29 competitions. A thorough three-stage review process was applied to all designs before  
30  
31 construction.  
32  
33  
34

35  
36 For the collection of the characteristics of each construction project, a list of questions was  
37  
38 distributed to the construction managers/supervisors responsible for each project and the  
39  
40 contractor's civil engineers. These questions concerned general information (e.g. location,  
41  
42 highway section and design office), the bridge's fundamental design parameters (e.g. number of  
43  
44 spans, construction method used, length of each span, width, height of piers) and the quantities of  
45  
46 concrete and reinforcing steel for each span and pier. After scrutinising the replies, on-site visits  
47  
48 were held to check and confirm the validity and accuracy of the data provided.  
49  
50  
51

52  
53 The final dataset includes three different types of bridges, distinguished by the use of  
54  
55 different construction methods as dictated by the varying landscape (mountainous, flat terrains,  
56  
57  
58  
59  
60

significant slopes, etc). Apart from the construction method, the dataset for each bridge also includes the superstructure material quantities i.e. concrete ( $V_c$ ), reinforcing steel ( $B_s$ ) and pre-stressed steel ( $B_p$ ), as well as basic design parameters i.e. the length of the span or cantilever ( $l$ ) and the deck width ( $b$ ). Details of the bridge superstructure dataset are presented in Table 1.

In order to take into account the difference of deck width among the bridges of the data sample, an adjusted length of the span or cantilever was also defined ( $l_{adj}$ ) as a function of the median value of the deck width for each construction method in the sample ( $b_{med}$ ) as per equation 1. This value equals 13.10 m for superstructures with precast beams, 13.50 m for superstructure with cast-in-situ box girders and 14.00 m for cantilever construction.

$$l_{adj} = l * \frac{b}{b_{med}} \quad (1)$$

Similarly, the collected dataset for 321 piers included the height of each pier,  $H$ , the corresponding concrete volume,  $V_c'$ , and the reinforced steel weight,  $B_s'$  (relevant ranges included in Table 2). Additionally, the length of the deck supported by each pier,  $l'$ , was calculated as the average length of the spans situated on both sides of the pier and this value was adjusted as previously (equation 2) to give  $l'_{adj}$ . In the following section, a thorough investigation of the datasets' characteristics is presented.

$$l'_{adj} = l' * \frac{b}{b_{med}} \quad (2)$$

### Multivariate data analysis

Multivariate analysis was undertaken to enable deeper understanding of the complexity of the interrelations between the variables of the datasets, i.e. the bridge type,  $b$ ,  $l$ ,  $V_c$ ,  $B_s$ ,  $B_p$ ,  $l_{adj}$  for bridge superstructure and  $H$ ,  $V_c'$ ,  $B_s'$  and  $l'_{adj}$  for bridge piers. Initially, the correlation matrices

1  
2  
3 provided in Figure 1 and Figure 2 provide a better picture of how the variables co-relate. In  
4  
5 particular, Figure 1 demonstrates the correlations between the superstructure variables while  
6  
7 similarly Figure 2 concerns the variables of the piers. From Figure 1, it can be observed that there  
8  
9 are pairs with strong, mainly nonlinear correlations. In Figure 2, the most apparent correlation  
10  
11 lies unsurprisingly between the concrete volume  $V_c$ ' and the reinforcement steel  $B_s$ ', while other  
12  
13 correlations (e.g. between piers height, H and concrete volume  $V_c$ ') are much more stochastic.  
14  
15  
16

17  
18 For further investigation of the correlations in the available dataset, the multivariate  
19  
20 datasets were analysed based on Andrews plots (Andrews, 1972) (Figure 3). Andrews plots  
21  
22 depict multivariate datasets to enable insights on the existence of possible correlations but with  
23  
24 no indication of their exact nature. Further information about Andrews plot can be found in  
25  
26 Garcia-Osorio and Fyfe (2006). In the specific form of the Andrews plot used in the present  
27  
28 study, each observation  $i$ , is represented by a function  $f(t)$  of a continuous dummy variable  $t$  over  
29  
30 the interval  $[0,1]$ . The Function  $f(t)$  is defined for the  $i$ -th observation in the dataset  $X$  as per  
31  
32 equation 3.  
33  
34  
35

$$f(t) = X(i,1) / \sqrt{2} + X(i,2) / \sin(2\pi t) + X(i,3) \cos(2\pi t) + \dots \quad (3)$$

36  
37  
38 In varying the value of  $t$  in equation 3, data points which are similar will behave similarly in that  
39  
40 the locus of their movement will be similar facilitating thus the identification of patterns as well as  
41  
42 outliers in the dataset. Figure 3 shows that at least four distinct clusters can be identified in the  
43  
44 superstructure's dataset.  
45  
46  
47  
48

49  
50 On the other hand, no particular clusters can be exposed in the Andrews plot for the piers'  
51  
52 dataset (Figure 4), revealing the stochastic nature of the interrelations among the selected  
53  
54 variables and validating the initial evidence provided earlier by the correlation analysis.  
55  
56 Concentrating on the piers' dataset and aiming to gain some insight into the type of the  
57  
58  
59  
60

1  
2  
3 interrelations, the normality of each variable as well as their possible fitting to the Weibull and  
4  
5 Lognormal distribution was checked. The relevant tests showed that none of the variables seem to  
6  
7 follow any of the theoretical distributions.  
8  
9

10 These findings suggest that standard regression analysis may not be a suitable analytical  
11  
12 framework, since the datasets do not fit to a theoretical distribution and thus this fundamental  
13  
14 assumption of regression analysis cannot be fulfilled. Moreover, the underlying relation between  
15  
16 the dataset variables possibly is of non-linear nature and of complex structure. Given the above,  
17  
18 the BoQ estimation problem requires a modelling approach based on ANNs, known for their  
19  
20 ability to handle complex 'mappings' from inputs to outputs. The experimental setup of the  
21  
22 ANNs used is presented in the following section.  
23  
24  
25  
26

### 27 **Application of the Feed-Forward Artificial Neural Network on the BoQ estimation**

28

29  
30 The estimation of a total BoQ for the superstructure and the piers of bridges is addressed by  
31  
32 combining the results of two suitably selected, trained and tested FFANNs. This combination is  
33  
34 able to adapt to the particularities of the two datasets, since the quality of ANN performance is  
35  
36 dependent on the quantity of training data and on how the data are presented to the network.  
37  
38 Therefore, several data-representation experiments with various network architectures, different  
39  
40 number of hidden layers, hidden nodes and transfer functions were conducted, resulting to the  
41  
42 structure presented in Figure 5.  
43  
44  
45  
46

47 It should be noted here that the current paper addresses the particularities of bridge cost  
48  
49 estimation through the following two methodological features:  
50  
51

- 52  
53 i. The use of binary/class/integer variables in the model building which enable the  
54  
55 introduction of bridge class features like the type of a bridge, and  
56  
57  
58  
59  
60

1  
2  
3 ii. The training of a different ANN for each main component (superstructure, piers) and  
4 subsequent combination of the results.  
5  
6

7  
8 These two elements ensure that the estimated models are accurate, robust and reliable, take  
9 into consideration realistic features in estimating bridges' cost and are also useful in project  
10 feasibility phase.  
11  
12  
13

14  
15 Starting from the configuration of the ANN corresponding to the superstructure, the deck  
16 width in meters ( $b$ ), the adjusted length of span or cantilever in meters ( $l_{adj}$ ) and the categorical  
17 variable representing the bridge type (Type) are the inputs to a hidden layer of 10 nonlinear  
18 neurons each of which has a log-sigmoid transfer function. Three linear functions for estimating  
19 the volume of concrete in  $m^3$  ( $V_c$ ), the weight of reinforcing steel in kg ( $B_s$ ) and the weight of  
20 pre-stressed steel in kg ( $B_p$ ) form the output layer of the ANN. Additionally, for the piers, the  
21 height ( $H$ ) and the adjusted length of the span supported by each pier ( $l'_{adj}$ ) are input into a  
22 hidden layer with 20 nonlinear neurons while the output layer estimates the volume of concrete in  
23  $m^3$  ( $V'_c$ ) and the weight of reinforcing steel in kg ( $B'_s$ ).  
24  
25  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37

38 The respective datasets were for both cases divided in three parts, namely, for training,  
39 validating and testing into typical proportions of 70%, 15% and 15% respectively. The training  
40 set was used by the Levenberg-Marquardt optimisation routine to update the weights of the  
41 connections between the layers with the aim to minimise the Mean Squared Error (MSE) between  
42 observations and predictions. The validation set was used to monitor the performance of the  
43 network during training against over-fitting /memorisation, while test set was used for unbiased  
44 evaluation of the model's predictive capabilities after the training process was completed. This  
45 type of FFANN has several advantages including being straightforward, powerful in mapping  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 nonlinear and stochastic interrelations within datasets, able to treat both continuous and  
4  
5 categorical (integer) data and easy for coding and testing (Karlaftis and Vlahogianni, 2011).  
6  
7

8 The convergence diagrams for the training, validating and testing process of the  
9  
10 complementary FFANNs (Figures 6 and 7) demonstrate the capability of the trained FFANNs to  
11  
12 model the interrelations among the dataset variables (starting from a random state) with a  
13  
14 substantially improved error component (reduced to  $10^8$  from  $10^{12}$ ), as the relevant MSE metric  
15  
16 denotes. The magnitude of performance of the gradient and the number of validation checks are  
17  
18 used to terminate the training. The gradient becomes very small as the training reaches a  
19  
20 minimum of the performance. Training stops after a number of successive epochs where the  
21  
22 validation performance fails to decrease (epoch 17 and onwards in Figure 6). As it can be  
23  
24 observed from Figure 7, the training process for the piers' FFANN requires 28 iterations, an  
25  
26 element possibly indicative of the complexity of the relevant dataset.  
27  
28  
29  
30  
31

32 The performance of the proposed FFANNs can be further exposed by the regression plots  
33  
34 for the three datasets (training, validating and testing). As can be observed in Figure 8, the  
35  
36 superstructure FFANN is capable of notably accurate BoQ estimations, since the correlation of  
37  
38 predictions and observations is very high for all sets ( $R \sim 0.99$ ) and the linear regression function  
39  
40 almost coincides with the ideal line. This is a clear indication of the model's value for practical  
41  
42 purposes.  
43  
44  
45

46 Similarly, the regression analysis of the correlation between the observations and  
47  
48 predictions made by the piers' FFANN is also very high (Figure 9) reaching an R value of  
49  
50  $R=0.99$  for training (Figure 9a). However, it can also be observed that the correlation diagram is  
51  
52 more scattered around the ideal correlation line for all sets (training, validation and testing), while  
53  
54 the correlation coefficient for the validation and especially for the testing set lies at 0.90 (Figure  
55  
56  
57  
58  
59  
60

1  
2  
3 9b) and 0.96 (Figure 9c) respectively. Although the results can be regarded as satisfactory, this is  
4  
5 an additional indication of the complexity of the interrelations between the variables of the piers.  
6  
7

8  
9 An additional indication for the FFANNs' performance can be obtained by checking the  
10  
11 distribution of errors; unbiased models are ideally expected to have normally distributed errors  
12  
13 with mean equal to zero. The close-to-normal distribution of the errors for the three sets (training,  
14  
15 validation and test sets) for both FFANNs as depicted in Figures 10 and 11, further verifies the  
16  
17 reliability of the training process and suggests unbiased estimation capabilities for both models.  
18  
19

20  
21 The above thorough evaluation of the developed FFANNs' capability to estimate the BoQ  
22  
23 for both the superstructure and piers of road bridges offers encouraging evidence on the  
24  
25 applicability and performance of such data-driven models in real-world problems. The final step  
26  
27 of the proposed methodological framework involves its comparison against parametric estimation  
28  
29 models. Such comparative analysis is provided in the next section.  
30  
31

### 32 33 **FFANNs' performance comparison to regression models**

34  
35

36 In order to check the performance of the developed FFANNs, apart from the tests already  
37  
38 presented, comparative statistics with standard regression models were also performed.  
39  
40 Specifically, the performance of the developed FFANNs was compared against the performance  
41  
42 of parametric linear regression models developed for the same data. The same test subset i.e. the  
43  
44 15% of the complete dataset was used in both cases. Two metrics of goodness-of-fit were used to  
45  
46 provide a clear picture of the accuracy of the alternative models: the coefficient of determination  
47  
48 ( $R^2$ ), which is a measure of the variability explained by the models and the Mean Absolute  
49  
50 Percentage Error (MAPE) which is an error metric. As presented in Table 3, the FFANN trained  
51  
52 to estimate the superstructure BoQ outperforms the respective linear regression model in all the  
53  
54 three construction methods and in both metrics.  
55  
56  
57  
58  
59  
60

1  
2  
3  
4

13  
14  
15  
16  
17  
18  
19  
20  
21  
22  
23  
24  
The comparative results for the piers' FFANN constitute an even stronger indication of the model's strengths and robustness. As indicated in Table 4, the FFANN demonstrates superior performance compared to the statistical models both in terms of the  $R^2$  and the MAPE. This is particularly evident for the estimation of the steel weight and can be attributed to the lack of data normality, which is a prerequisite for the development of reliable linear regression models. The difference observed in the MAPE value between the FFANN for the superstructure and the one for the piers is also worth noting; in the case of piers the MAPE is significantly higher compared to the equivalent values for the superstructure, an additional evidence of the prediction difficulty for the piers' dataset.

25  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
The above presented results provide strong evidence on the FFANNs' potential on predicting bridges' BoQ when used as surrogate mechanisms early in the design stage. Given the complex interrelationships among the variables for BoQ estimation and taking into account the overall very satisfactory computational performance of the developed models, it can be concluded that in the context of road bridge projects, the developed FFANNs are capable to provide reliable estimates of the material quantities required which in turn, can be used to yield cost estimates of improved accuracy.

### 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60 **Conclusions**

Developing a reliable cost estimate for large-scale road transport projects is a challenge for any authority or organisation, especially at the preliminary design phase, where only a general idea exists about what the project will entail. Aiming to enhance the accuracy of such preliminary cost estimates, two FFANNs were trained and tested on actual data from 68 concrete road bridges with the aim to reliably predict the BoQ of bridge superstructure and piers (concrete, pre-stressed steel and reinforcing steel) based on variables normally known even in the early implementation

1  
2  
3 stages. Specifically, the variables used as input to the superstructure's FFANN were the deck  
4 width, the adjusted length of span or cantilever and the type of the bridge (with precast beams,  
5 with cast in situ deck or cantilever construction). Similarly, for the piers' FFANN, the input  
6 variables were the height of the pier and the adjusted length of span supported. As the relevant  
7 performance analysis demonstrates, the developed FFANN model captures very well the complex  
8 interrelations in the dataset and as a result of its strong generalization capability, it provides  
9 reliable estimations of the final material quantities. An accurate cost estimation can be then  
10 achieved by multiplying the properly selected material unit prices with the predicted material  
11 quantities. Furthermore, following comparison of the FFANNs' performance against the  
12 performance of the respective linear regression models, it became apparent that the use of  
13 artificial intelligence resulted in an improved level of accuracy. Therefore, the proposed cost  
14 estimation model represents a useful and reliable tool for the construction industry as it enables  
15 planners to reach informed, despite early, decisions for technical and economic planning of  
16 concrete bridge projects. Furthermore, the proposed surrogate model provides evidence of the  
17 potential usefulness of ANNs in civil infrastructure planning and design. Similar extended  
18 databases could be developed to include the remaining bridge elements (e.g. foundations and  
19 abutments), other road infrastructure elements (culverts, underpasses and overpasses) as well as  
20 motorway bridges constructed with different materials (e.g. steel girders and reinforced-concrete  
21 slabs) or construction methods (e.g. incremental launching) and lead to additional cost estimation  
22 models utilizing FFANNs. This research also highlights potential future directions for the field of  
23 construction software, as the artificial intelligence of this computational paradigm is also suitable  
24 for integration in the currently available software for infrastructure design and management.
