Running Head: Vascular cell responses to TLR ligands

Main text word count (introduction to discussion): 2,522 words, 13,958 characters

Abstract

Background Atherosclerosis is potentiated by stimulation of Toll-like receptors (TLRs), which serve to detect pathogen-associated molecular patterns (PAMPs). However little is known of which PAMPs may be present in atheroma, or capable of stimulating inflammatory signalling in vascular cells.

Materials and Methods DNA extracted from human carotid atheroma samples was amplified and sequenced using broad-range 16S gene specific primers to establish historical exposure to bacterial PAMPs. Responsiveness of primary human arterial and venous endothelial and smooth muscle cells to PAMPs specific for each of the TLRs was assessed by measurement of interleukin-8 secretion and E-selectin expression.

Results Extracts of atheromatous tissue stimulated little or no signalling in TLR-transfected HEK-293 cells. However, sequencing of bacterial DNA amplified from carotid atheroma revealed the presence of DNA from 17 different bacterial genera, suggesting historical exposure to bacterial lipopeptide, lipopolysaccharide and flagellin. All cells examined were responsive to the ligands of TLR3 and TLR4, poly-inosine:cytosine and lipopolysaccharide. Arterial cells were responsive to a wider range of PAMPs than venous cells, being additionally responsive to bacterial flagellin and unmethylated cytosine-phosphate-guanosine DNA motifs, the ligands of TLR5 and TLR9 respectively. Cells were generally unresponsive towards the ligands of human TLR7 and TLR8, loxoribine and single stranded RNA. Only coronary artery endothelial cells expressed TLR2 mRNA and responded to the TLR2 ligand Pam₃CSK₄.

Conclusions Vascular cells are responsive to a relatively diverse range of TLR ligands and may be exposed, at least transiently, to ligands of TLR2, TLR4, TLR5 and TLR9 during the development of carotid atheroma.

Keywords: Atherosclerosis, Toll-like receptor, 16S gene, bacteria

Introduction

Atherosclerosis is a chronic inflammatory disease of the arteries, characterised by the activation of endothelial cells to express inflammatory mediators and the subsequent recruitment of monocytes into the artery wall, which may differentiate to form fat-laden foam cells [1]. Among candidate inflammatory stimuli that may potentiate this condition, stimulation of Toll-like receptors (TLRs) has emerged as a key factor in atherogenesis [2].

The ten human TLRs serve to initiate inflammatory signalling in response to the detection of conserved pathogen associated molecular patterns (PAMPs). TLR2, in conjunction with heterodimerisation partners TLR6 or TLR1, recognises di-acyl or tri-acyl bacterial lipopeptides (BLP), respectively. TLR3 recognises double stranded RNA, while TLRs 7 and 8 recognise single stranded RNA motifs, indicating a role for these receptors in anti-viral defence [3]. TLRs 4, 5 and 9 recognise bacterial lipopolysaccharide (LPS), flagellin and the unmethylated cytosine-phosphate-guanosine (CpG) DNA motif, respectively, while no ligand has yet been identified for TLR10. In each case, engagement of TLRs with their respective ligands leads to the induction of inflammatory signalling and the resultant expression of inflammatory mediators such as interleukin (IL)-8, tumour necrosis factor (TNF)- α and E-selectin [4].

Mice deficient in a shared signalling adaptor of the TLRs, myeloid differentiation factor-88 (MyD88), have been shown to be resistant to atherogenesis [5,6], while genetic deletion of TLR2 or TLR4 also leads to a reduction in aortic plaque burden of between 30% and 60% in mouse models of atherosclerosis [5-8]. Accordingly, experimental

stimulation of TLR2 or TLR4 signalling via recurrent injection of either BLP or LPS markedly accelerates atherogenesis [8-10]. In human atheromatous tissue, expression of TLRs 2, 4 and 5 is markedly upregulated compared to healthy artery, and TLR2 and TLR4-expressing cells within plaque were shown to co-stain for activated nuclear factor (NF)- κ B [11].

The likely stimulants of TLRs in the diseased artery wall remain to be clearly identified. However, as many previous studies have reported the presence of bacterial products within human atheroma [12-15], and seropositivity to common viruses has also been associated with atherosclerosis [16,17], it is likely that vascular cells may be exposed to diverse TLR ligands of both bacterial and viral origin during the development of atheroma.

As little information exists on the responsiveness of primary human vascular cells to PAMPs specific for each of the TLRs, and since arterial tissues are more susceptible to the development of atherosclerosis than venous tissues, we aimed to establish the range of TLR-ligands that may be capable of stimulating expression of IL-8 and E-selectin in primary venous and arterial endothelial and smooth muscle cells, and sought evidence for the presence of these PAMPs in human atheromatous tissue.

Materials and Methods

Culture of primary vascular cells

Vein rings from healthy saphenous vein harvested for coronary artery bypass graft were cultured in 50:50 Waymouths:F12/Ham solution (Invitrogen, Paisley, UK) in 15% Foetal

Calf Serum. Explanted human vein smooth muscle cells (HVSMC) were split using trypsin/EDTA (Sigma, Poole, UK) and transferred to 75 cm² tissue culture flasks for use between passages 1 and 3. Collection of venous tissue was performed with informed consent in accordance with local ethical guidelines (REC # 07/S0704/48). Human primary aortic (HAEC) and umbilical vein (HUVEC) endothelial cells and arterial smooth muscle cells (HASMC) were purchased from Cascade Biologics (Paisley, UK) and cultured in M200 medium, or M231 according to supplier's recommendations. Human primary coronary artery endothelial cells (HCAEC) were purchased from Cambrex (East Rutherford, USA) and cultured in EGM2-MV according to supplier's recommendations. In each case, cells were cultured in 5% CO₂ at 37°C and were used for experiments between passages 3 and 7.

Challenge of vascular cells with PAMPs

Pam₃CSK₄, PolyI:C, *Bacillus subtilis* flagellin, loxoribine, single stranded RNA and endotoxin-free bacterial CpG DNA were from Invivogen (Toulouse, France). LPS of *Escherichia coli* R1 (NCTC 13114) and *Porphyromonas gingivalis* was a kind gift of Professor Ian Poxton (University of Edinburgh). Vascular cells were plated at 2 x 10⁴ cells per well of 96-well plates and allowed to adhere for 24 h prior to challenge. Cells were then challenged with medium alone (DMEM containing 1% serum), 100 ng/ml Pam₃CSK₄, 25 µg/ml PolyI:C, 100 ng/ml LPS, 1 µg/ml flagellin, 1 mM loxoribine, 5 µg/ml single stranded RNA or 10 µg/ml CpG DNA, in triplicate wells. After 18h, culture supernatant was assessed for IL-8 concentration by ELISA (R&D Duoset, Minneapolis, USA). Alternatively, endothelial cells were cultured with PAMPs for 4 h before

measurement of cell-surface E-selectin expression. In other experiments, J774A.1 macrophages were challenged with the same concentrations of PAMPs and supernatant TNF- α was measured at 4 h by L929 bioassay [18].

Cell-based E-selectin ELISA

HUVECs, HAECs and HCAECs treated with PAMPs for 4h in 96-well plates were washed twice in phosphate-buffered saline (PBS) and fixed with 4% paraformaldehyde in PBS at 4°C for 15 minutes. Wells were then washed twice in PBS and blocked with 1% bovine serum albumin in PBS for 30 minutes. Plates were washed three times, and biotinylated E-selectin-specific antibody (Hycult Biotechnology, Uden, Netherlands), was added to each well at a concentration of 500 ng/ml in reagent diluent (20 mM Tris, 150 mM NaCl, 0.1% BSA, 0.05% Tween-20). Wells were then washed and 1:200 dilution of streptavidin-horse-radish peroxidase (R&D) in reagent diluent was added for 30 minutes. Wells were then washed and 100 μ l of 3,3',5,5-tetramethylbenzidine reagent (Sigma) added. Absorbance of each well was measured at 450 nm using a spectrophotometer.

TLR RT-PCR

RNA was prepared from 1×10^6 vascular cells plated in 6-well tissue culture plates using an RNEasy kit (Qiagen, Crawley, UK). cDNA was prepared from extracted RNA using oligo-dT primer and reverse transcriptase (Stratagene, La Jolla, USA). For PCR amplification of cDNA specific for β -actin or TLRs 1-9, 1 μ l of cDNA was amplified in a 30 μ l reaction volume using Go-Taq reaction master mix (Promega, Southampton, UK).

Thermal cycling consisted of 3 minutes at 94°C, followed by 27 cycles of 94°C for 30 s, 55°C for 30s and 72°C for 1 min and a final extension at 72°C for 10 minutes. The primers used to amplify each target gene are listed in Table 1.

16S PCR identification of bacterial DNA in atheromatous tissue

Atheromatous plaques (n=3) were obtained from routine carotid endarterectomy, performed due to transient ischaemic attack, with informed consent according to local ethical procedures (LREC 04/S1101/48). Care was taken to avoid contamination of the excised material which was stored at -20°C prior to analysis. Plaque tissue was homogenised with 1.0 mm glass beads in a mini beadbeater (Biospec, Bartlesville, USA) before lysis and DNA extraction using TRIzol reagent (Sigma). PCR was then performed using consensus primers 27f and 1387r that amplify the 16S rRNA gene of diverse bacteria, as described previously [19]. A positive control PCR containing 10 ng of *E. coli* genomic DNA was included in each experiment. PCR products were cloned using the TOPO TA Cloning Kit (Invitrogen), and selected clones were sequenced in one direction using the 357F primer to obtain a minimum of 500 bp of sequence from a variable region of the 16S rRNA gene. All clone sequences were then compared against the EMBL/GenBank sequence databases using the BLAST algorithm. Clones sharing 98% identity with a known sequence were positively identified as belonging to that species. Sequences with a lower percentage identity were analysed using the PHYLIP suite of programmes to determine the phylogenetic position of the clone. For all 16S-work, strict anti-contamination procedures were employed. Separate rooms were used for sample preparation, PCR reactions and analysis of reaction products. Filter tips were used at all

stages and for each set of samples being analysed and negative controls (sterile water) were included.

TLR-transfection assay

HEK-293 cells were plated in 96-well plates at 2×10^4 cells per well and transfected after 24 h using Genejuice (Novagen, Nottingham, UK), with 30 ng of human TLRs 2, 4 (co-expressing MD-2), or 5 (Invivogen), 30 ng of pCD14, 10 ng of NF- κ B sensitive luciferase-reporter construct (pELAM) and 20 ng of renilla-luciferase reporter construct [20]. Three days after transfection, cells were challenged for 18 h with PAMPs or atheroma samples. Reporter levels were measured using Promega Dual-Glo reagent kit and normalised to co-transfected renilla expression. Promoter expression is represented as fold induction relative to cells cultured in medium alone +/- SD. Human carotid atheroma samples were ground under liquid nitrogen in sterile cryovials before resuspension in 10 volumes (per weight) of DMEM / 1% foetal calf serum (FCS) prior to sonication for 2 minutes, vortexing for 2 minutes and addition to transfected cells.

Results

Responsiveness of primary vascular cells to TLR ligands

Primary human vascular cells were exposed to PAMPs specific for each of the functional human TLRs at concentrations that were found to induce maximal induction of TNF- α secretion in TLR-competent macrophages (Figure 1), or as described previously [21]. Secretion of IL-8 and expression of E-selectin were measured as markers of cellular

inflammatory activation as these mediators have been implicated in the progression of atherosclerosis in previous studies [22,23]. A significant increase in IL-8 secretion was observed from venous SMCs in response to LPS and PolyI:C and from venous ECs in response to LPS, PolyI:C and CpG DNA, but not other PAMPs (Figure 2). Arterial ECs and SMCs exposed to the same ligands increased IL-8 secretion in response to treatment with PolyI:C, LPS, flagellin and CpG DNA (Figure 3). Significant upregulation of E-selectin expression by arterial ECs was observed in response to LPS, PolyI:C and flagellin, while an E-selectin response was observed in venous ECs exposed to only PolyI:C or LPS (Figure 4). Only coronary artery ECs responded to Pam₃CSK₄ stimulation with increased IL-8 secretion and E-selectin expression.

Qualitative analysis of TLR mRNA expression by vascular cells

In order to establish whether mRNA corresponding to each of the TLRs was expressed in primary vascular cells, qualitative RT-PCR was performed using primers specific for each of the 9 functional TLRs (Figure 5). HUVECs expressed detectable mRNA for all TLRs other than TLR2. HAECs and HASMCs expressed mRNA for all TLRs other than TLR1 and TLR2, while HVSMCs expressed mRNA for all TLRs other than TLR1, TLR2 or TLR7. Remarkably, HCAECs expressed mRNA specific for all of the 9 TLRs examined. THP-1 macrophages were found to express detectable mRNA for all TLRs other than TLR3. No bands were detected from PCR reactions containing RNA that had not been reverse transcribed (data not shown).

Investigation of bacterial 16S DNA signatures in human carotid atheroma

In order to gain information on the potential prior exposure of atheromatous tissue to bacterial ligands of the TLRs, DNA was extracted from three atheromatous plaques and amplified by PCR using primers specific for the bacterial 16S DNA gene. 58 cloned PCR products were sequenced, of which 56 could be identified to bacterial genus or species level. The most frequently isolated clones corresponded to *Acinetobacter* species, followed by *Brevundimonas* species and *Lysobacter enzymogenes*. A further 14 bacterial genera were identified at lower frequencies (Table 2). No amplification product was detected in control experiments using identical reagents with sterile water replacing template DNA.

Biological activity of TLR2, TLR4 and TLR5 ligands in human atheroma

Given the likelihood that developing plaques are at some stage exposed to ligands of TLR2, TLR4 and TLR5, we next aimed to determine whether such PAMPs may remain detectable in human atheroma. To achieve this, endarterectomy samples were homogenised and applied to HEK-293 cells transfected with NF- κ B-sensitive reporter and TLR2, TLR4 or TLR5. *P. gingivalis* LPS, *E. coli* LPS and flagellin were detected only in cells expressing TLR2, TLR4 or TLR5, respectively, confirming the purity of these reagents and also the specificity of the TLR-reporter assay (Figure 6A). No stimulants of TLR4 or TLR5 could be detected in the atheroma samples, although in one plaque sample there was a significant increase in reporter activity in cells expressing TLR2, but not other TLRs, indicating the presence of a TLR2 ligand in this sample (Figure 6B).

Discussion

Since the observation that TLR-signalling is a key modulator of atherosclerosis in animal models [5-10], two main questions that remain to be addressed in this area are: what is the range of TLR-ligands that may stimulate inflammatory signalling in human vascular cells, and what might be responsible for stimulating TLR-signalling in human atheromatous tissue?

Our results suggest that arterial cells are responsive to a relatively wide range of PAMPs, particularly those derived from bacteria, including ligands of TLRs 2, 4, 5 and 9. Notably, the identification of responsiveness of arterial cells to flagellin appears to be novel, and adds weight to previous reports of TLR5 protein expression in internal mammary artery and intestinal microvessels [11,24]. Uniquely among the vascular cell types examined, endothelial cells from the coronary artery also expressed TLR2 and were responsive to bacterial lipopeptide, in accordance with previous reports [25,20]. The observation that arterial cells are responsive to a wider range of bacterial PAMPs than venous cells may be of relevance regarding the increased susceptibility of arteries to plaque formation compared to veins, as chronic bacterial infection has been reported to correlate with increased atherosclerosis risk [26,27], and immunohistochemical approaches have revealed the presence of diverse bacterial antigens in a high percentage of atheroma samples [13,28-30].

We next aimed to examine the possibility that atheromatous tissues may be exposed to the bacterial ligands of the receptors we identified to be functional in arterial tissues in this study, namely TLRs 2, 4, 5 and 9. Although extracts from atheromatous samples stimulated no TLR4- or TLR5-dependent signalling in the TLR-transfection assays, we

cannot exclude the possibility that small numbers of bacteria expressing LPS or flagellin may nevertheless be present in the samples as the limit of sensitivity of the assay is around 10^3 bacterial cells per ml. It is more likely, however, that biologically active PAMPs delivered to the artery wall exert their atherogenic properties only transiently, being soon degraded and thereby losing their inflammatory potential, such as by proteolysis of flagellin or deacylation of LPS [31]. Indeed, an emerging consensus is that bacterial antigens and DNA, rather than live bacteria, accumulate within atheroma [12,13,32].

Seeking alternative evidence of exposure of atheroma to bacterial PAMPs, we examined bacterial 16S DNA signatures from atheroma, as 16S gene containing DNA fragments have been shown to remain intact for years in tissues after degradation of other bacterial macromolecules [33]. Confirming the results of several recent studies, we found an abundant diversity of bacterial 16S DNA signatures in human atheroma, extending the list of species discovered in atheroma to include *Acinetobacter* and *Brevundimonas* species [14,15,30,34-36]. Notably, all of the bacteria identified in this and previous studies are thought to express ligands of TLR2 and TLR9, while endotoxin of *Acinetobacter* species stimulates TLR4-signalling and approximately half of the genera identified in our study are thought to be motile and express flagellin (Table 2). The 16S data therefore supports the notion that during the development of human atheroma, such tissues may be exposed, at least transiently, to ligands of TLR2, TLR4, TLR5 and TLR9.

In summary, we have shown that arterial cells are typically responsive to a wider range of PAMPs than venous cells and that it is likely that arterial cells may be exposed, at least transiently, to bacterial ligands of TLRs 2, 4, 5 and 9 during the development of carotid

atheroma. While the observations presented here do not allow any conclusion to be drawn as to whether or not bacteria potentiate atherosclerosis, it seems likely that if this is the case, no single organism or source of bacterial antigens is likely to be identified as a unique contributor to atherogenesis.

Figure 1: Tumour necrosis factor (TNF)- α secretion from J774A.1 macrophages exposed to pathogen associated molecular patterns (PAMPs)

J774A.1 macrophages were challenged with medium alone (Ctrl), Pam₃CSK₄ (Pam3), Poly-Inosine:Cytosine (PolyI:C), lipopolysaccharide (LPS), flagellin (Flag), Loxoribine (Lox), single stranded RNA (ssRNA) or cytosine-phosphate-guanosine (CpG) DNA at the concentrations indicated in the materials and methods. Supernatant TNF- α was measured after 4 h. Results are presented as mean \pm SD of triplicate wells and are representative of four independent experiments. ** P < 0.01 vs cells cultured in medium alone.

Figure 2: Interleukin (IL)-8 secretion from human umbilical vein endothelial cells (HUVECs) and human venous smooth muscle cells (HVSMCs) exposed to PAMPs

HUVECs (A) and HVSMCs (B) were challenged with medium alone (Ctrl), Pam₃CSK₄ (Pam3), PolyI:C, LPS, flagellin (Flag), Loxoribine (Lox), single stranded RNA (ssRNA) or CpG DNA at the concentrations indicated in the materials and methods. IL-8 secretion was measured after 18 h. Results are presented as mean \pm SD of triplicate wells and are representative of three independent experiments. ** P < 0.01 vs cells cultured in medium alone.

Figure 3: IL-8 secretion from human aortic endothelial cells (HAECs), coronary artery endothelial cells (HCAECs) and arterial smooth muscle cells (HASMCs) exposed to PAMPs

HAECs (A), HCAECs (B) and HASMCs (C) were challenged with PAMPs as described in the legend to Figure 1. IL-8 secretion was measured after 18 h. Results are presented as mean +/- SD of triplicate wells and are representative of three independent experiments. * P < 0.05 vs cells cultured in medium alone.

Figure 4: E-selectin expression by HAECs and HUVECs exposed to PAMPs

HAECs (A), HCAECs (B) and HUVECs (C) were challenged with PAMPs as described in the legend to Figure 1. Expression of E-selectin was measured by cell-surface ELISA after 4 h. Results are presented as mean +/- SD of triplicate wells and are representative of at least two independent experiments. * P < 0.05 vs cells cultured in medium alone.

Figure 5: Qualitative analysis of Toll-like receptor (TLR) mRNA expression in vascular cells

cDNA from primary human vascular cells or THP-1 macrophages was subjected to PCR (27 cycles) using primers specific for β -actin (β), or TLRs 1-9, as indicated. Products were single and of the expected size.

Figure 6: TLR-assay of extracts from atheromatous plaques

HEK-293 cells were transfected with nuclear factor κ B sensitive promoter construct (pELAM) and CD14 alone, or with additional TLR2, TLR4/MD2 or TLR5. Transfected

cells were then challenged with 100 ng/ml *P. gingivalis* LPS, 100 ng/ml *E. coli* LPS or 1 µg/ml *B. subtilis* flagellin (A). Alternatively, transfected cells were exposed to homogenate from human carotid atheromatous tissue ground under liquid nitrogen and resuspended at 1:10 (weight:volume) in DMEM / 1% FCS (B). Promoter expression was then measured at 18 h and is represented as fold induction relative to cells cultured in medium alone +/- SD. Results shown are representative of three separate experiments. ** P < 0.01 vs cells cultured in medium alone.

Table 1: Primers used for RT-PCR and 16S directed sequencing

<u>Gene</u>	<u>Primer Sequence</u>	<u>Product size</u>
β -actin	TACCCCATCGAGCACGGCA TGGGCACAGTGTGGGTGAC	289 bp
TLR1	GCATCTTCCATTTTGCCATT TTGTTGTGGGACAAATCCAA	304 bp
TLR2	GGCCAGCAAATTACCTGTGT CTCCAGCTCCTGGACCATAA	320 bp
TLR3	AGCCGCCAACTTCACAAG AGCTCTTGGAGATTTTCCAGC	327 bp

1	1.7	<i>Porphyrobacterium tepidarius</i>	98.5	AY568495	?
1	1.7	Uncultured beta proteobacterium	99	DQ230944	?
2	3.5	Unclassified clones	-	-	?

DNA extracted from three atheromatous plaques obtained from routine carotid

endarterectomy was amplified using broad-range 16S gene specific primers. 58 cloned

products were sequenced, of which 56 could be identified by BLAST searches with >97% identity to established bacterial species or genera. Listed also is an indication of whether these organisms are thought to be motile or otherwise.
