ABSTRACT

We present multiobject spectroscopy of galaxies in the immediate (Mpc-scale) environments of four low-power ($L_{1.4\,\mathrm{GHz}} \lesssim 10^{25}\,\mathrm{W\,Hz^{-1}}$) radio galaxies at $z \sim 0.5$, selected from the *Subaru/XMM–Newton Deep Field*. We use the spectra to calculate velocity dispersions and central redshifts of the groups the radio galaxies inhabit, and combined with *XMM–Newton* (0.3–10 keV) X-ray observations investigate the L_X–σ_v and T_X–σ_v scaling relationships. All the radio galaxies reside in moderately rich groups – intermediate environments between poor groups and rich clusters, with remarkably similar X-ray properties. We concentrate our discussion on our best statistical example that we interpret as a low-power (Fanaroff–Riley type I) source triggered within a subgroup, which in turn is interacting with a nearby group of galaxies, containing the bulk of the X-ray emission for the system – a basic scenario which can be compared to more powerful radio sources at both high ($z > 4$) and low ($z < 0.1$) redshifts. This suggests that galaxy–galaxy interactions triggered by group mergers may play an important role in the life-cycle of radio galaxies at all epochs and luminosities.

Key words: galaxies: evolution – cosmology: observations.

1 INTRODUCTION

In recent years, feedback mechanisms from radio galaxies [i.e. galaxies which host radio-loud active galactic nuclei (AGN)] have become the method of choice for curtailing the bright end of the galaxy luminosity function in models of galaxy formation, since models without feedback tend to overproduce the number of very luminous galaxies compared to what is observed (e.g. Bower et al. 2006). Many high-redshift radio galaxies lie in (proto)cluster environments (e.g. Venemans et al. 2003) and the energy provided by their radio jets (the bulk kinetic power of the radio jets is several orders of magnitude larger than the radio luminosity; e.g. Rawlings & Saunders 1991) is sufficient to shut down star-forming activity throughout a cluster (Rawlings & Jarvis 2004). Furthermore, it has been suggested that powerful radio sources may be triggered by galaxy–galaxy interactions during the merging of subcluster units (Ellingson, Yee & Green 1991; Simpson & Rawlings 2002).

Lower luminosity sources are also believed to be vital in shaping the galaxy luminosity function by providing a low-power, but high-duty cycle, mode of feedback (e.g. Croton et al. 2005; Bower et al. 2006; Best et al. 2006). This mode of feedback appears to be most common in the most massive galaxies, which are, of course,

preferentially located in the centres of galaxy clusters. Therefore, there appears to be significant interplay between the formation and evolution of both the radio sources and their cluster environments. Studying the environments of low-power radio sources is likely a promising route towards understanding radio galaxy feedback. However, while the radio galaxy itself can influence the thermodynamic history of its environment (i.e. by depositing energy), the picture is complicated by global environmental processes such as the merging of subcluster units, which can temporarily boost the X-ray luminosity and temperature of the intracluster medium (ICM) (e.g. Randall, Sarazin & Ricker 2002), making such systems more readily detectable in X-ray surveys (a matter of caution in using such X-ray detected systems as cosmological probes). It is essential to perform detailed studies of the radio, optical, and X-ray properties of putative dense regions in the cosmic web to ascertain how mergers and radio source activity affect the life-cycle of clusters.

The luminosity and temperature of a cluster are known to follow a scaling relationship (the L_X–T_X relation), $L_X \propto T_X^\alpha$, where α has been measured in the range ~ 2.7–3 (Edge & Stewart 1991; David, Jones & Forman 1995; Allen & Fabian 1998; Markevitch 1998; Arnaud & Evrard 1999). This is at odds with that expected for clusters formed by gravitational structure formation, with $L_X \propto T_X^2$ (Kaiser 1986). It is thought that the disparity is due to the interruption of cooling by feedback from active galaxies, which can impart

★E-mail: j.e.geach@durham.ac.uk

energy via outflow shocks (e.g. from radio-jets or superwinds), or by performing work by subsonically inflating bubbles in the ICM (ICM; Sijacki & Springel 2006). Best et al. (2005) suggest that, given the short lifetimes of radio-loud AGN (10–100 Myr), episodic triggering must occur in order for feedback to quench cooling. However, much lower luminosity sources ($L_{1.4\,\mathrm{GHz}} < 10^{25}\,\mathrm{W\,Hz^{-1}}$) can impart energy into the intergalactic medium with a higher duty cycle than the more powerful, and rarer, sources (Best et al. 2006).

McLure et al. (2004) have recently constructed a sample of radio galaxies at $z \sim 0.5$ which spans three orders of magnitude in radio luminosity, but even the faintest of these sources are close to the Fanaroff–Riley (FR) break (Fanaroff & Riley 1974) and it is desirable to push to even fainter radio luminosities to fully investigate the radio galaxy–cluster symbiosis. In this paper, we present multi-object spectroscopy of galaxies around four low-power ($L_{1.4\,\mathrm{GHz}} < 10^{25}\,\mathrm{W\,Hz^{-1}}$) radio galaxies at $z \sim 0.5$ in the *Subaru/XMM–Newton Deep Field* (SXDF) (Sekiguchi et al. 2001). The resultant spectroscopic redshifts allow us to investigate the environments of these radio sources which could provide a large proportion of the local volume averaged heating rate if the AGN luminosity function is flat below $L_{1.4\,\mathrm{GHz}} \sim 10^{25}\,\mathrm{W\,Hz^{-1}}$ (Best et al. 2006). We combine these data with X-ray observations of the radio galaxies' environments in order to investigate the global environmental properties – namely the L_X–σ_v and T_X–σ_v relations. This parameter space can be used as a diagnostic of the thermodynamic history of groups or clusters, since if an AGN is significantly feeding energy back into the ICM, then the group or cluster might be expected to deviate from the standard empirical $L_\mathrm{X}(T_\mathrm{X})$–$\sigma_\mathrm{v}$ relation for massive systems. Throughout we adopt a flat geometry with $\Omega_\mathrm{m} = 0.3$, $\Omega_\Lambda = 0.7$ and $H_0 = 100\,h$ km s^{-1} Mpc^{-1} where $h = 0.75$. All magnitudes in this paper are on the AB scale.

2 OBSERVATIONS AND REDUCTION

2.1 Sample selection and spectroscopy

Targets were selected from an early version of the 1.4-GHz Very Large Array radio mosaic presented in Simpson et al. (2006, hereafter S06), and listed in Table 1. The limited red sensitivity of the Low Dispersion Survey Spectrograph (LDSS-2, Allington-Smith et al. 1994) placed an upper limit of $z \sim 0.7$ as appropriate for our study, so we selected radio sources whose optical counterparts are resolved and have $19 < R < 20.5$, since the tightness of the Hubble diagram for radio galaxies allows redshifts to be estimated from a single magnitude, and we aim to target moderate redshift environments (Cruz et al. 2007). Colour–magnitude diagrams were produced for 2.5-arcmin regions around each radio galaxy and the four optically brightest radio galaxies whose environments displayed a red sequence were selected for spectroscopic follow-up. This selection was simply performed 'by eye' – if the colour–magnitude

diagram displayed an overdensity of points at $18 < m_\mathrm{RG} < 20.5$ with tight scatter in colour space. Note that local X-ray properties were not taken into account when choosing the target radio galaxies – this is simply an optical selection of radio galaxies.

Masks were designed using the LDSS-2 mask preparation software, with objects along the red sequence (typically using a colour cut of width 0.3 mag) included in the input file (Fig. 1). This software allows relative priorities to be assigned to targets, which were set to be equal to the magnitudes of the galaxies, to increase the likelihood of successfully determining redshift.

Observations were conducted using the medium-red (300 lines mm^{-1}, $\lambda_0 = 5550$ Å) grism of LDSS-2 in a multiobject mode on the 6.5-m Magellan telescope in Las Campanas, Chile over the nights of 2003 October 17–20 (effective resolution 13.3 Å). The MOS frames were trimmed for overscan, flat-fielded, rectified, cleaned and wavelength-calibrated using a sequence of Python routines (D. Kelson, private communication); sky-subtraction and spectrum extraction were performed in IDL. Due to a lack of standard star observations, for flux-calibration and to correct for the wavelength-dependent response of the detector, we extracted $BVRi'z'$ photometry for the targets from the SXDF catalogue. Using the five sources in each mask with the strongest signal-to-noise ratio (S/N), we fit mask-specific response curves to the 1D spectra, which are then applied to each extracted target spectrum. Although flux-calibration and response-correction are not necessary for redshift determination via cross-correlation, we perform these steps in order to present a sample of the spectra in Fig. 2.

2.2 X-ray data

The SXDF incorporates a deep, large-area X-ray mosaic with *XMM–Newton*, consisting of seven overlapping pointings covering $\sim$1.3-deg^2 region of the high Galactic latitude sky with an exposure time of 100 ks in the central field (in separate exposures) and 50 ks in the flanking fields (see Table 2). Four of the pointings were carried out in 2000 August, and the remaining three were made in 2002 August and 2003 January.

All the *XMM–Newton* EPIC data, that is, the data from the two MOS cameras and the single PN camera, were taken in a full-frame mode with the thin filter in place. These data have been reprocessed using the standard procedures in the most recent *XMM–Newton* SCIENCE ANALYSIS SYSTEM (SAS) v6.5. All the data sets where at least one of the radio galaxies was seen to fall within the field of view (FOV) of the detectors were then analysed further. JEG 3 was observed in pointings SDS-1a (PN), SDS-1b (PN) and SDS-6 (M1, M2, PN) (part of the field lies off the edge of the MOS FOVs in SDS1a and SDS1b). Both JEG 2 and JEG 4 were observed in pointing SDS-7 (MOS 1, MOS 2, PN). Finally JEG 1 was observed in pointing SDS-2 (MOS 1, MOS 2, PN). Periods of high background were filtered out of each data set by creating a high-energy 10–15 keV light curve of single events over the entire FOV, and selecting

Table 1. Summary of radio galaxy targets. IDs, positions and fluxes are taken from an early version of the 1.4-GHz VLA radio mosaic presented in S06. In this paper, for convenience, we shorten IAU identifications of the radio galaxies to JEG 1–4. We quote radio luminosities here for completeness; however, we discuss the redshift determination in Section 3.2.

Figure 1. $R - z'$ versus z' field-corrected colour–magnitude diagrams for each mask. Photometry was extracted from the SXDF catalogue by choosing all galaxies within an aperture of radius 2.5 arcmin centred on the brightest target galaxy. Colours are measured in 2-arcsec apertures, and we also indicate a secondary colour, $i' - z'$ (arbitrarily chosen), to emphasize the location of the red sequence as larger points. The colours of targeted galaxies in this work are indicated by the larger open circles.

times when this light curve peaked above 0.75 count s^{-1} (for PN) or 0.25 count s^{-1} (for MOS). It is known that soft proton flares can affect the background at low energies at different levels and times than at high energies (e.g. Nevalainen, Markevitch & Lumb 2005). This was not seen to be the case in the data sets analysed here, however, as full energy-band (1–10 keV) light curves (extracted from off-source regions) showed essentially identical times of flaring activity as the high-energy light curves. The high-background times in each data set are seen to be very distinct and essentially unchanging with energy band. The exposure times of the resulting cleaned relevant data sets are given in Table 2.

Source spectra were extracted from the relevant data sets from apertures centred on the source positions. Extraction radii, estimated from where the radial surface brightness profiles were seen to fall to the general surrounding background level, were set to 50, 21, 36 and 47 arcsec for JEG 1, 2, 3 and 4, respectively. Note that the surface brightness profiles were co-added for all three EPIC cameras for improved S/N. Standard SAS source-detection algorithms uncovered a large number of X-ray sources both point like and extended. Data due to contaminating sources lying within the extraction regions are needed to be removed from the spectra. This proved necessary only for JEG 3, where two sources were detected just within the extraction region. Data from the two sources were removed to a radius of 28 arcsec (and the extraction area is thus reduced by ∼10 per cent). Background spectra were extracted from each cleaned data set from an annulus of an inner radius 60 arcsec and outer radius 180 arcsec around each position. As point sources were seen to contaminate these larger-area background spectra, the data from these detected sources were removed from the background spectra to a radius of 60 arcsec. We have verified that all the X-ray sources are clearly extended using both simple (sliding box) and more sophisticated wavelet analysis techniques. The possibility that JEG 2 is an unresolved source complex cannot of course be completely ruled out, given its low S/N. Given the relative weakness of all of the X-ray sources, we consider that the extraction radii used

are close to optimum to provide the best S/N in the extracted spectra. Ancillary Response Files (ARFs) containing the telescope effective area, filter transmission and quantum efficiency curves were created for the cluster spectra (taking into account the fact that the extraction regions are extended), and were checked to confirm that the correct extraction area calculations (complicated with the exclusion of contaminating point sources, etc.) had been performed. Finally, Redistribution Matrix Files (RMFs) were generated. These files describe, for a given incident X-ray photon energy, the observed photon energy distribution over the instrument channels. These can be used in conjunction with the ARFs to perform X-ray spectral analysis – we use the most commonly used analysis package: XSPEC. The source spectral channels were binned together to give a minimum of 20 net counts per bin. A detailed discussion of the X-ray spectral fitting and the results is given in Section 3.4.

3 ANALYSIS

3.1 Colour–magnitude diagrams

In Fig. 1, we plot the $R - z'$ versus z' colour–magnitude relations (CMRs) for each field, which have been constructed from the photometry of all galaxies within 2.5 arcmin of each radio-galaxy target. We correct the colour–magnitude diagrams for field contamination using a method similar to Kodama et al. (2004) and Kodama & Bower (2001), which we will briefly describe here. First, colour–magnitude space is divided into a coarse grid [$\Delta z' = 2$, $\Delta(R - z') = 0.8$], and the number of galaxies within each grid-square counted: N_{ij}^{gal}. An identical count is performed for a control field, $N_{ij}^{\mathrm{control}}$, where control galaxies are selected within an aperture of an identical radius to the one used for each target mask, but centred on a random point on the sky (but within the catalogue). We then assign the ij^{th} colour–magnitude bin the probability that the galaxies within it are field members: $P_{ij} = N_{ij}^{\mathrm{control}}/(N_{ij}^{\mathrm{gal}} + N_{ij}^{\mathrm{control}})$. For each galaxy in colour–magnitude space, we pick a random number, p, in
Figure 2. Successfully cross-correlated spectra for the radio galaxy field of (top to bottom panel) JEG 1–4. The spectra are plotted in the rest frame. As a guide, we identify as the dotted vertical lines the spectral features [O II], K, H, Hδ, G, Hγ and Hβ. We do not plot wavelengths bluewards of 3500 Å or redwards of 5000 Å (rest frame) since in these regimes the response and S/N of the spectra do not allow accurate analysis. Note that the shaded region highlights a sky-absorption feature.

Table 2. Overview of the *XMM–Newton* observations. Tabulated are the Field IDs, the centres of the pointings and the exposure times of the relevant high-background-cleaned data sets for each camera: MOS 1, MOS 2 and PN. Note that the coordinates are in J2000.

Field	RA ($^{h\,m\,s}$)	Dec. ($^{\circ\,\prime\,\prime\prime}$)	Exposure time [MOS 1 MOS 2 PN] (ks)
SDS-1a	02 18 00	−05 00 00	– – 40
SDS-1b	02 18 00	−05 00 00	– – 42
SDS-2	02 19 36	−05 00 00	47 48 40
SDS-6	02 17 12	−05 20 47	49 49 47
SDS-7	02 18 48	−05 20 47	40 41 35

the interval {0,1} and compare it to P_{ij}; a galaxy is removed from the diagram if $p < P_{ij}$. In order to reduce effects of cosmic variance (e.g. randomly picking another cluster or void as the control sample), we build up an average probability map by repeating the control sample count and probability calculation 10 times around different random positions in the catalogue.

There are clear red sequences around all four radio galaxies, and to emphasize this, we also plot a secondary colour $i - z'$, and the locations of galaxies in colour space are targeted for spectroscopy. The secondary colour-cut is chosen merely to highlight the red sequence.

3.2 Redshift determination and velocity dispersions

For redshift determination, we use the VELOCITY code of Kelson et al. (D. Kelson, private communication), which cross-correlates target and template spectra. The errors are determined from the topology of the cross-correlation peak (i.e. the width of a Gaussian profile fit to the peak in the cross-correlation spectrum) and the noise associated with the spectrum, typically in the range 30–210 km s^{-1}. We present spectra of the target radio galaxies which have been successfully cross-correlated and shifted to the rest frame in Fig. 2. In Table 3, we list the coordinates, z' magnitudes and redshifts of successfully cross-correlated targets, with the radio galaxies highlighted.

To calculate the velocity dispersions of each cluster, we follow the iterative method used by Lubin, Oke & Postman (2002) and others (e.g. Willis et al. 2005). Initially, we estimate that the cluster central redshift is that of the target radio galaxies, and select all other galaxies with $|\Delta z| < 0.06$ in redshift space. We then calculate the biweight mean and scale of the velocity distribution (Beers, Flynn & Gebhardt 1990) which correspond to the central velocity location, v_c, and dispersion, σ_v of the cluster. We can use this to calculate the relative radial velocities in the cluster frame: $\Delta v = c(z - z_c)/(1 + z_c)$. The original distribution is revised, and any galaxy that lies $>3\sigma_v$ away from v_c, *or* has $|\Delta v| > 3500$ km s^{-1} is rejected from the sample and the statistics are re-calculated. The final result is achieved when no more rejection is necessary, and the velocity dispersion and cluster redshift can be extracted. The results are presented in Table 4, with 1σ errors on the cluster redshift and dispersion corresponding to 1000 bootstrap resamples of the redshift distribution.

In Fig. 3, we plot the redshift distribution of those galaxies for which we performed successful cross-correlations. We also plot the velocities of those galaxies within $|\Delta v| < 2000$ km s^{-1} of the cluster central redshift, overlaid with standard Gaussian profiles. JEG 3 is the largest sample of cluster galaxies (in part due to the large number of galaxies targeted in this field). JEG 1 and JEG 4 (at similar redshifts) have relatively few members after the process of rejection described above. JEG 2 has a high velocity dispersion, indicating a non-relaxed system, despite the fairly prominent red sequence in this region. In part, the high velocity dispersion might be attributed to an outlying galaxy in the velocity distribution, but as we discuss in Section 3.3, JEG 2 might be part of a larger, more complicated structure than a simple group.

3.3 Environmental richness estimates

Although a rigorous spectroscopic environmental analysis of the clusters is not feasible with the sample sizes in this study, we can make an estimate of the richness of the clusters by some simple counting statistics using the photometric information from the SXDF catalogue. The $N_{0.5}$ measure is perhaps the best tool for a first-order quantitative analysis of a cluster environment – it only relies on an approximate cluster redshift (in order to calculate the angular radius of the counting aperture), and a satisfactorily deep photometric catalogue (Hill & Lilly 1991). It has been shown to correlate well with the more complex B_{gg} statistic (Longair & Seldner 1979), which is a more rigorous measure of the density of galaxies

Table 3. Spectroscopic targets with total z'-band magnitudes and cross-correlated redshifts. Redshift uncertainties are derived from the topology of the cross-correlation peak. The radio galaxy is highlighted in bold type in each case.

Table 4. Spectroscopic, environmental and X-ray properties of target clusters. The cluster redshift z_c and line-of-sight velocity dispersion σ_v are calculated using the biweight mean and scale of the distribution (Section 3.2), with 1σ errors corresponding to 1000 bootstrap resamples of the redshift distribution. The environmental richness statistics (see Section 3.3) are the $N_{0.5}$ counting statistic and B_{gc}, the amplitude of the galaxy-cluster cross-correlation function. We also tabulate the results of fitting thermal (MEKAL) plasma models to the X-ray spectra of the clusters (see Section 3.4 for details). The uncertainties represent 90 per cent for a single interesting parameter, determined during the spectral fitting with the XSPEC software.

	Redshift properties			Environmental properties		X-ray properties (0.3–10 keV)				
ID	z_c	σ_v (km s^{-1})	f^a_{mem}	$N_{0.5}$	B_{gc} (Mpc$^{1.77}$)	kT (keV)	Z ($Z_\odot$)	L_X (10^{36} W)	χ^2/N_{dof}	Net counts

^{a}Fraction of members associated with the radio galaxy environment for successful redshifts.

Figure 3. Relative velocity distribution of galaxies where a successful redshift determination was performed. Relative velocities are in the cluster frame, over a range ± 2000 km s^{-1}. The insets show the distribution in redshift space, over a wider velocity range. We overlay Gaussian profiles based on the fitted velocity dispersion in each case.

in space when spectroscopic data are lacking, but when the shape of the luminosity function is known (see uses in e.g. Farrah et al. 2004; Wold et al. 2000, 2001). In physical terms, B_{gg} is the amplitude of the galaxy–galaxy spatial correlation function: $\xi(r) = B_{gg} r^{-\gamma}$, where γ is typically 1.8–2.4 (Lilje & Efstathiou 1988; Moore et al. 1994; Croft, Dalton & Efstathiou 1999), though the low end of the range is typically chosen, with $\gamma = 1.77$ (e.g. Yee & Ellingson 2003). Both these measures can be translated to the more familiar Abell richness scale.

$N_{0.5}$ is calculated by choosing a target and counting the number of galaxies within 0.5 Mpc in the magnitude range $\langle m, m + 3 \rangle$, where m is the magnitude of the target galaxy, which in this case we choose to be the radio galaxies. A field correction is applied by subtracting the expected number of galaxies in this magnitude range from a control field (this control field was different for each target, chosen to be centred on a random point, >1 Mpc from the radio galaxy). Note that the $N_{0.5}$ statistic will be inaccurate in cases where there is strong differential evolution between the radio galaxy luminosity and companion cluster galaxies, but this can be compensated for by choosing the second or third brightest galaxy in the aperture and

applying the same method. More importantly, it is clear from the spectroscopic results that the $N_{0.5}$ statistic is contaminated by line-of-sight structures not associated with the physical environment of the radio galaxies. This is particularly evident for JEG 4 – the slightly higher redshift structure suggested by the number of $z \sim 0.4$ galaxies have magnitudes and colours that not only reinforce the original red-sequence selection, but also will be included in the $N_{0.5}$ calculation. Thus, it is important to note that this method can only provide a very rudimentary environmental analysis – a more sophisticated method is required.

For this reason, we also calculate B_{gc} – where 'gc' stands for 'galaxy-cluster centre'. This is a potentially useful statistic: derived solely from photometry, it has been shown to be in excellent agreement with its spectroscopic counterpart, and can be used as a predictor for global cluster properties such as the velocity dispersion, virial mass and X-ray temperature (Yee & Ellingson 2003). Thus, we have another parameter to compare with our spectroscopically derived cluster velocity dispersions and X-ray observations, as well as a quantitative description of the richness of the radio galaxies' environments.

A full derivation of the B_{gc} statistic was made by Longair & Seldner (1979), and has been used in a practical sense by several other authors (see Yee & López-Cruz 1999; Wold et al. 2000, 2001; Farrah et al. 2004), so we will not give a detailed procedure here, but the form of the statistic is given by

$$B_{gc} = \frac{\rho_g A_{gc}}{\Phi(m_{lim}, z) I_\gamma} d_\theta^{\gamma-3}, \tag{1}$$

where ρ_g is the surface density of field galaxies brighter than a limit m_{lim}, d_θ is the angular diameter distance to z, I_γ is an integration constant ($I_{\gamma=1.77} \sim 3.78$) and $\Phi(m_{lim}, z)$ is the integral luminosity function to a luminosity corresponding to m_{lim} at z. A_{gc} is the amplitude of the angular correlation function, calculated by comparing the net excess of galaxies within 0.5 Mpc of the target with the number of background sources expected for an identical aperture in the field: $A_{gc} = (N_{net}/N_{bg})((3 - \gamma)/2)\theta^{\gamma-1}$. The conversion to B_{gc} effectively deprojects A_{gc} from the celestial sphere into 3D space.

Perhaps the most important factor to consider is the choice of luminosity function, although B_{gc} is reasonably tolerant of incorrect parameters (as long as they are within ~ 20 per cent of their true values). We estimate the shape of the luminosity function at $z = 0.35$ and 0.65 by using the semianalytic catalogue output of the Millenium Simulation[1] (Springel et al. 2005; Bower et al. 2006).

---

[1] http://galaxy-catalogue.dur.ac.uk.

At each epoch, we fit a Schechter function to the absolute (simulated) R-band magnitude counts, fixing the faint-end slope $\alpha = -0.9$. The resulting $(M_\star, \phi_\star)$ are $(-20.87$ mag, 0.0042 Mpc^{-3}) and $(-20.65$ mag, 0.0021 Mpc^{-3}) at $z = 0.35$ and 0.65, respectively. The relevant luminosity function used in equation (1) is evaluated from $M_\star + 3$ to $M_\star - 3$, where the faint end is in a relatively flat part of the distribution, and the bright end is expected to include most of the cluster galaxies (note that changing these limits by ± 1 magnitude does not change the value of B_{gc} by more than 1σ). The results are presented in Table 4.

It is important to note that JEG 2 appears to have an environment almost consistent with the field (although, as noted the $N_{0.5}$ statistic is likely to suffer contamination). This is inconsistent with the apparent red sequence around the radio galaxy, which would suggest a moderate overdensity. However, we have seen that the very high velocity dispersion for this group, and structure in the velocity distribution might affect the richness estimates if the group is spatially spread out. JEG 1 and JEG 4 are moderately rich environments (they have very similar levels of overdensity, although note that JEG 4 is contaminated by a slightly higher redshift line-of-sight structure, and so its true richness is likely to be slightly lower), consistent with rich groups. JEG 3 is also an overdensity, but the statistics suggest that the cluster is no more rich than JEG 1 or JEG 4. Thus, the radio galaxy selection is detecting moderately rich groups of galaxies.

3.4 X-ray spectral fitting

The X-ray spectral fitting package XSPEC was used to fit X-ray spectral models to the cluster spectra. In terms of X-rays from galaxy clusters, it is commonly believed that the emission is predominantly due to the hot cluster gas trapped in the potential well, absorbed by the hydrogen column density within our own Galaxy (i.e. little in the way of internal cluster absorption is expected). The spectra therefore were fitted with a standard model comprised of a MEKAL hot plasma emission spectrum, together with a WABS photoelectric absorption model (Morrison & McCammon 1983). Due to the small number of counts, the hydrogen column of the absorption was fixed at the Galactic hydrogen column density in the line of sight to the *Subaru* pointings: $N_H = 2.55 \times 10^{20}$ atoms cm^{-2} (Dickey & Lockman 1990). Also the redshifts were fixed at the values given in Table 4. The temperature and metallicity were left free to optimize. Acceptable spectral fits were found for all the clusters (though only a small number of counts is seen from JEG 2), and these results are given in Table 4. We present the best-fitting gas temperature and metallicity (with respect to the solar value), the errors being 90 per cent for a single interesting parameter, and the (0.3–10 keV) absorption-corrected X-ray luminosity. Also tabulated are the best-fitting χ^2 values and the number of degrees of freedom. For none of the clusters were there sufficient counts to warrant the use of a more complex model. We attempted to rebin the spectra into five counts per bin, with a fit based on Cash statistics (i.e. not subtracting the background in order to maintain counting statistics, Cash 1979); however, this does not provide stronger constraints on T or Z compared to the adopted method. The data and best-fitting models are shown in Fig. 4.

4 DISCUSSION

With the exception of JEG 2, the radio galaxies in each of our fields have environmental properties consistent with moderately rich groups at $z \sim 0.5$, in terms of their density statistic and X-ray properties. Despite the presence of a clear red sequence in the field of JEG 2 (Fig. 1), a simple $N_{0.5}$ environmental measure suggests that the environment is consistent with the field. However, it is likely that this is in fact a cluster of similar richness to JEG 1, JEG 3 and JEG 4 given that there are several nearby galaxies with colours and spectroscopic redshifts close to the radio galaxy. The low-number statistics for this system makes it difficult to make any robust comments about the radio-galaxy environment, except that this is probably a dynamically young group. There is some evidence for a sheet at $z \sim 0.65$ (Simpson et al., in preparation) and JEG 2 may simply lie in an overdensity within this stucture. A large projected distribution of red galaxies around this group would in part explain the failure of the B_{gc} statistic to detect an overdensity: it could be possible that the control aperture itself is contaminated by the larger stucture.

Our observations of JEG 1 and JEG 4 also do not contain enough confirmed spectroscopic members at the radio galaxies' redshifts to comment on their environments from a spectroscopic standpoint. The wide-angle radio tail of JEG 1 suggests rapid movement through a dense medium (S06), consistent with a group–group merger (e.g. Jetha, Hardcastle & Sakelliou 2006). There is insufficient spectroscopic data to confirm this though. Furthermore, in the case of JEG 4, our results could be affected by a background group, although it is not clear that this is contributing significantly to the X-ray luminosity. This slightly more distant group could also be reinforcing the strength of the red sequence (Fig. 1), and is a cautionary point regarding selection in this way.

4.1 Scaling relations

The X-ray luminosities derived by fitting thermal models to the X-ray spectra are remarkably constant over our radio galaxy sample, with the environment of JEG 3 the hottest and intrinsically the most luminous (we note that the small number of counts seen from JEG 2 results in a poorly constrained model). In Fig. 5, we compare these clusters' properties with the L_X–T_X relation of Helsdon & Ponman's (2000) study of galaxy groups and low-luminosity clusters, more luminous and massive systems from Wu, Xue & Fang (1999), as well as more intermediate-redshift ($z < 0.6$) X-ray-selected groups/clusters from the *XMM*-Large Scale Survey (*XMM*-LSS; Willis, Pacaud & Pierre 2006).

First, the four clusters all have high L_X and high T compared to the group sample, indicating that they bridge the gap between groups and rich clusters – a relatively unexplored region of parameter space. This is likely due to selection effects, thus there is potential in investigating these types of environment using a selection technique similar to the one outlined in this work. However, we note that the radio-selected environments are quite similar to X-ray-selected groups/clusters at similar redshifts, detected in the *XMM*-LSS (Willis et al. 2006). We show also the disparity between the slopes of the L_X–T_X relation for groups (Helsdon & Ponman 2000) and rich clusters (Wu et al. 1999), which differ by a factor of ~ 2. This is probably a real effect – the steepening of the slope for groups reflects the fact that these systems have a propensity to exhibit deviations from the relation seen for the more massive systems due to processes other than cooling (Ponman, Cannon & Navarro 1999; Willis et al. 2005). Note that all the empirical relations found for groups and clusters are steeper than that expected for pure gravitational structure formation (Kaiser 1986); this implies that feedback as a source of energy input is important over all scales of clusters, but is more dominant in the low-mass systems.
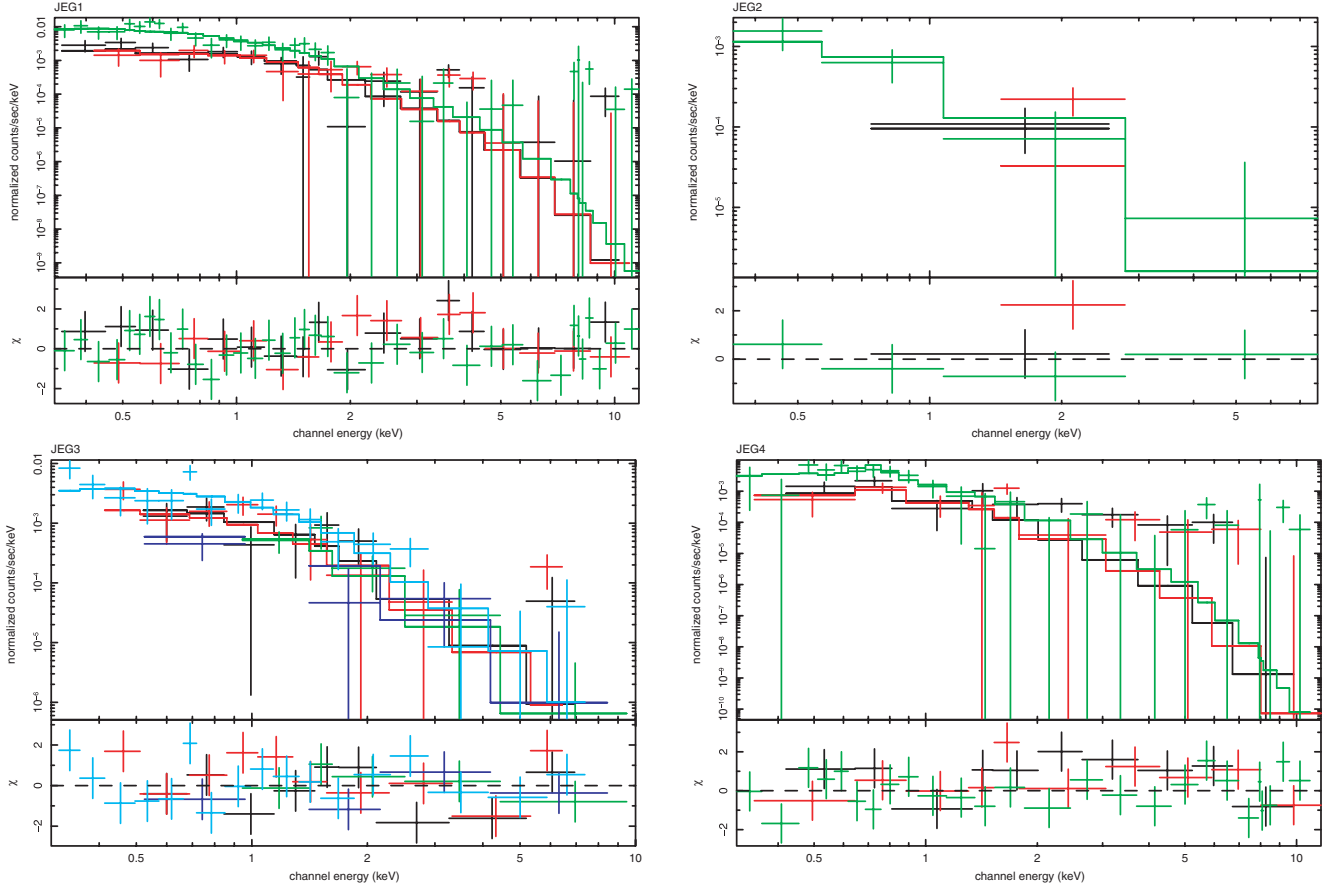

Figure 4. The *XMM–Newton* EPIC spectra of (row-wise from the top left-hand panel) JEG 1–4, together with the best-fitting thermal plasma model fitted using XSPEC. χ^2 differences are shown in the lower panels of each plot. The colour-codings correspond to the MOS 1, MOS 2 and PN cameras and field pointings (see Table 2 and Section 2.2). For JEG 1 (SDS-2), JEG 2 (SDS-7) & JEG 4 (SDS-7) black is MOS 1, red is MOS 2 and green is PN. For JEG 3 black is PN (SDS-1a), red is PN (SDS-1b), green is MOS 1 (SDS-6), blue is MOS 2 (SDS-6) and cyan is PS (SDS-6). The resulting cluster parameters of L_X and T_X are presented in Table 4.

One can also compare the cluster X-ray luminosity and velocity dispersion with the L_X–σ relations for these environments (Fig. 5). Although our small number statistics provide only loose constraints on our environmental parameters, all our environments appear to have slightly large velocity dispersions compared to the temperature of the intracluster gas, although this is not statistically significant. Once again, the velocity dispersions and temperatures reveal that these radio galaxies inhabit intermediate environments between groups and clusters. A similar picture is revealed by the L_X–σ_v relationship, with all clusters having slightly large σ_v for their L_X. This is in good agreement with the observed velocity dispersions for other radio/optically selected samples (e.g. Rasmussen et al. 2006; Popesso et al. 2007).

In Fig. 6 we show true colour optical images of all four environments, along with the positions of spectroscopic members and radio and X-ray contours. This shows both the red sequence galaxies and the extended X-ray emission, as well as the location of the radio galaxy in each case. For the remainder of the discussion, we concentrate on JEG 3, which has a spectroscopically confirmed sample large enough to comment on the Mpc-scale environment of the radio galaxy.

4.2 Discussion of JEG 3

Optically, the radio galaxy is intriguing: it appears to be morphologically disturbed, with a blue and red part, suggestive of a recent

or ongoing interaction triggering star formation. In fact, a closer inspection of the spectra (and images) provides unambiguous evidence that the blue component is actually a strongly lensed background AGN or starburst galaxy at $z = 1.847$ – not associated with the group (Fig. 7). This high-redshift object does not affect our results in any way, other than the fact that without the spectroscopic confirmation, this might be classified as a merger from the optical images alone. In terms of the radio emission, we are confident that the majority of the emission originates in the lensing source – that is, the original selection of this target is still secure (the morphology and position of the radio emission support this, see Fig. 6). In terms of the impact from X-ray emission from the lensed galaxy, we also estimate that our measurements of the X-ray luminosity of the group will not be affected. The main bulk of the X-ray emission appears to be offset from the radio galaxy itself (Fig. 6) and the data were cleaned for point source emission prior to spectral fitting (Section 2.2). In the case that the point source is not cleaned, we estimate the impact on our measurement of L_X: if the lensed galaxy is a starburst, then we expect the X-ray luminosity to be of the order of $\sim 2 \times 10^{34}$ W (based on an X-ray stack of $z \sim 2$ BM/BX galaxies, Reddy & Steidel 2004), although this will be boosted by the lens. If it is an AGN, then we might expect the X-ray luminosity to be higher by a factor of ~ 2 (Lehmer et al. 2005). In both cases, this has a negligible impact on our results.

The most obvious feature of JEG 3's environment is the apparent spatial offset between the radio galaxy itself and the bulk of galaxies
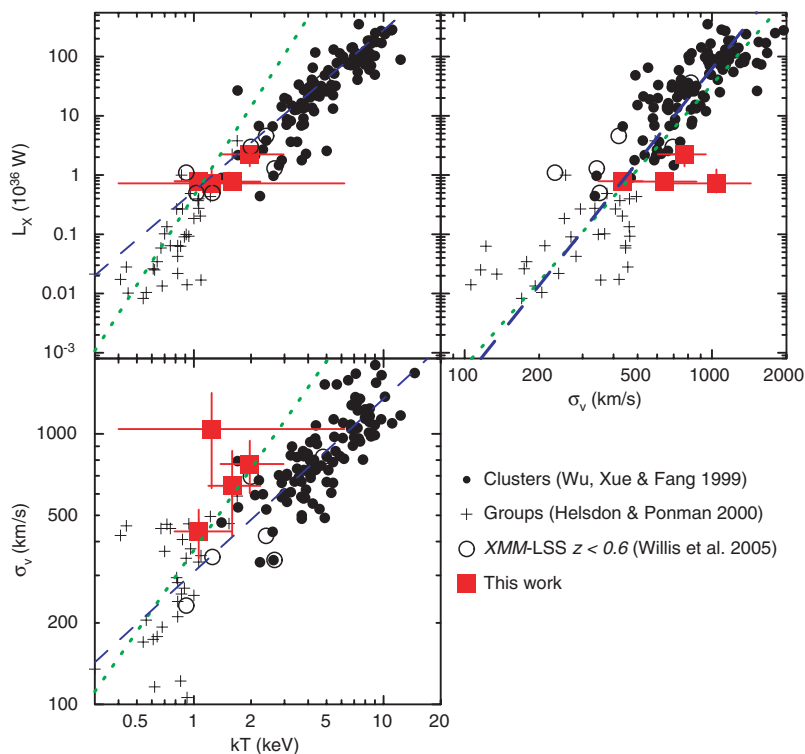

Figure 5. The correlation of global cluster properties: (top left-hand panel) L_X–T_X (bottom left-hand panel) T_X–σ_v (top right-hand panel) L_X–σ_v. We compare our results with both rich clusters (Wu et al. 1999) and poor groups (both the 'loose' and 'compact' samples from Helsdon & Ponman 2000), as well as more recent results from the *XMM*-LSS (Willis et al. 2005). In all parameter spaces shown, the sample in this work occupy the intermediate space between the rich and poor samples and are similar to the *XMM*-LSS sample. The dotted lines are the relationships derived for the groups sample from Helsdon & Ponman (2000), and the dashed lines show the equivalent relations derived using the rich cluster data from (Wu et al. 1999). For clarity, we do not plot errors on the literature points (but these are taken into account in the linear fits). The X-ray data from this work are corrected for aperture losses. To estimate this, we extrapolate a King surface brightness profile of the form: $S(r) = S_0[1 + (r/r_{core})^2]^{-3\beta+0.5}$. Assuming $\beta = 0.5$ and $r_{core} = 200$ kpc, we find that the apertures recover ~80 per cent of the total flux, extrapolating to $2r_{core}$. All points are corrected to our adopted cosmology, with $H_0 = 75$ km s^{-1} Mpc^{-1}.

at the group redshift of 0.649 (Fig. 6), coincident with the dominant source of X-ray emission. The galaxy's radio lobe morphology is suggestive of infall through a dense ICM towards this higher density region. In Fig. 6, we represent the relative velocities of galaxies about the central redshift, indicating objects with $\pm\Delta v$. Note that there are two other radio galaxies in this group; one ~0.5 arcmin to the west of the target radio galaxy, and the other [FR type II (FR II) source] several more arcminutes farther to the west. Spectroscopic observations of these objects (Simpson et al., in preparation) show that neither of them is associated with the structure surrounding JEG 3. These radio galaxies are not associated with the $z \sim 0.65$ structure identified around the radio galaxy in this work (see Simpson et al., in preparation).

The radio galaxy appears to be associated with a small group interacting with the main body of the structure, thus it is not unreasonable to associate the triggering of the radio galaxy with this interaction. This is a scenario which has been seen in other radio galaxy environments, at both high and low redshifts, and over a wide range of radio powers (Simpson & Rawlings 2002). For example, the high-redshift radio galaxy TN J1338−1942 ($z = 4.1$, Venemans et al. 2003) belongs to a 'protocluster', but is offset from the centre of the overdensity. Similarly at low redshift, the FR II source Cygnus A ($z = 0.056$) is involved in a cluster–cluster merger (e.g. Ledlow, Owen & Miller 2005), with the radio-source offset from the main overdensity (Owen et al. 1997). X-ray mapping of this cluster revealed hot (presumably) shocked gas between the two main peaks of the X-ray emission in the two subcluster units (Markevitch et al.

1999), consistent with the model of head-on cluster merging. These well-studied radio galaxies are examples of the most-luminous objects at their redshifts, whereas the luminosities of the radio galaxies in this work are modest in comparison. Triggering within interacting subcluster units seems to be responsible for a proportion of radio galaxies, and this appears to have been happening at all epochs, and over a wide range of luminosities.

The triggering of the radio galaxy could have occurred via galaxy–galaxy interactions in its immediate group, while the X-ray emission seems to be centred on the richer group in which gas is plausibly being heated by gravitational processes. However, there is a further complication to the L_X–T_X relationship, in that the outcome of the interaction between two subgroups is a 'boosting' of the X-ray luminosity and temperature of the resulting cluster (Randall et al. 2002). In general, this will temporarily (i.e. for a few 100 Myr) enhance both L_X and T_X, before the cluster settles down to its equilibrium value. It is not clear what stage of interaction this environment is in. Given the relatively large offset between the X-ray emission and the radio galaxy, we postulate that this is in an early stage. In these environments, it appears that we are witnessing radio galaxy activity and group–group merging/interaction at the same time. Although this may hint at radio galaxy triggering in the cluster assembly phase, this does not imply that all clusters containing a radio galaxy are in an unrelaxed state – most-relaxed clusters also contain a central radio source. This is interesting in that it appears that radio galaxy activity can be important in the thermodynamic history of the cluster environment over a wide range
Figure 6. Here we present true colour image constructed from *Subaru BVi*-band 8×8-arcmin^2 images centred on the target radio galaxies JEG 1–4 (orientation: the north is up and the east to the left-hand side). In addition to the colour information, we overplot as contours the radio galaxy morphology from the VLA images (white solid line), and X-ray (0.3–10 keV) contours (green dashed line). The radio contour levels have been chosen to emphasize the lobe morphology (note that these are VLA B-array maps with a beam size of 5×4 arcsec^2 with PA $= 170°$, see S06), and the X-ray contours are slightly smoothed with a Gaussian kernel of width ~ 1 arcmin and at ~ 2, 3, 5 and 7σ above the background in the vicinity of the environment. Finally, using the redshift data, we highlight galaxies which have $|\Delta v| < 2000$ km s^{-1} relative to the cluster redshift. We plot positive values of Δv as the open circles and negative values as the open squares.

of scales (i.e. groups to massive clusters) and various stages of development.

Following the assumption made in equation (4) of Miley (1980), and adopting an expansion speed of 0.03–0.15c (e.g. Scheuer 1995), we estimate the jet power of JEG 3 to be of the order of 0.5–1×10^{36} W, which is comparable to the X-ray luminosity of the cluster (the expected contribution to the X-ray luminosity from the radio galaxy itself is not significant). Although the similarity in power is likely coincidental, it is interesting, because the radio output of this low-power source appears to be sufficient to balance the radiative cooling of the gas. However, it is unlikely that the radio galaxy could keep up this balance over a long period: this mechanical injection will end long before the main merger between the two groups stops

imparting energy to the system, given the expected time-scales of radio activity ($\lesssim 10^8$ yr, Parma et al. 2002) which will likely be the dominant event in the pre-equilibrium thermodynamic history of the cluster. Nevertheless, since the radio-galaxy appears to have been triggered early in the lifetime of the cluster (the centres of the radio and X-ray emission are separated by ~ 200 kpc, Fig. 6), it could be important for providing significant energy input to the ICM, and therefore raising its entropy.

5 SUMMARY

We have presented multiobject (LDSS 2) spectroscopy, combined with radio (VLA) and X-ray (*XMM–Newton*) observations
Figure 7. Spectra of components 'a' and 'b' of the radio galaxy in the field of JEG 3 – SXDF-iS-170569. The inset grey-scale images are 6 × 6-arcsec^2 *Subaru* SuprimeCam thumbnails in *BVRiz* bands, clearly showing the distinction between a red component 'a' and blue component 'b'. The spectra unambiguously identify 'b' with a galaxy at $z = 1.847$, strongly lensed by the foreground component 'a'. The emission lines at the very blue end of the spectrum 'b' are C IV, O III] and C III] in emission, securing the redshift. Fe III is seen in absorption at 2587 and 2600 Å.

of the Mpc-scale environments of a sample of low-power ($L_{1.4\,\mathrm{GHz}} \lesssim 10^{25}$ W Hz^{-1}) $z \sim 0.5$ galaxies in the *Subaru/XMM–Newton Deep Field* (S06).

The radio galaxies targeted all appear to inhabit moderately rich groups, with remarkably similar X-ray properties, with JEG 3 (VLA 0033 in S06) being the hottest and residing in the richest environment. A statistical interpretation of the environment of JEG 2 (VLA 0011 in S06) would suggest that it does not belong to a cluster, but this could be in part due to the spatial distribution of the galaxies – the other evidence that this is a relatively rich group is compelling: there is a relatively strong red sequence and extended X-ray emission seen at this location (suggesting a gravitationally bound structure), and the spectroscopic data (although dominated by small number statistics) suggest that this is indeed a group, or part of a much larger structure, albeit one that is not relaxed. Also, three of the radio galaxies exhibit extended lobe morphology that suggests movement through a dense ICM, again hinting that these systems are undergoing dynamical evolution.

Our analysis concentrates on the environment of JEG 3, which presents us with a 'snapshot' of radio-galaxy and cluster evolution at $z \sim 0.65$. Overall, this is the richest environment we have studied, and the spectroscopic data reveal substructure: the radio galaxy belongs to a small group of galaxies which appears to be interacting (merging) with a larger group of galaxies. The X-ray emission for this system is associated with the richer, but radio-quiet group. We postulate that the radio emission has been triggered by a galaxy–galaxy merger within its Local Group. Although this may be providing some feedback to the ICM (indeed, the radio output is capable of balancing the overall radiative cooling), the eventual group–group interaction will boost the overall X-ray luminosity and temperature. This process will take longer than the lifetime of the radio-source, and so might be the dominating event in the thermodynamic fate of the environment. This scenario is not dissimilar to the situation with other radio galaxies at both high redshift and in the local Universe. Moreover, radio-triggering within subcluster units appears to be important for a proportion of the radio galaxy population over all epochs and luminosities.
