### ABSTRACT

#### A Comparison Of Clinico-Biological And Genetic Markers In Sporadic Breast Cancer In Different Populations

Wafa Makky Jonathan Ronald Nichols MSc (U.E.A)

The aim of this thesis is to examine the hypothesis that breast cancer exhibits ethnic differences in incidence, age of presentation and aggressiveness.

Two approaches were used:

Firstly, International data was examined to find if differences in the age of presentation of breast cancer existed between low and high breast cancer incidence populations.

Secondly, selected pathobiological parameters and genetic markers, chosen to act as surrogate markers of tumour behaviour, were examined in breast cancers from Western Region of Saudi Arabia, Leicester Asians and Leicester Europeans.

Analysis of International data showed countries with the lowest incidence of breast cancer to have a significantly lower mean age of onset than countries with the highest incidence. The mean age of onset in the Western Region was less than Leicester Asians and Leicester Europeans. Statistically significant differences in ASIR were found between the study groups that varied with age.

Breast cancers from Western Region and Leicester Asian women, when compared to the Leicester Europeans, were found to have a more aggressive profile of clinicopathological markers, but a less variable and possibly less aggressive nuclear morphometry.

Molecular alterations at the markers studied appeared to be related to age, 16q exhibiting more Loss of Heterozygosity in older groups and p53 in the younger groups. 6q also showed differences in Loss of Heterozygosity with respect to age, but these differences varied between the populations studied.

The results are consistent with a "two disease" model of breast cancer. It is proposed that the low age of onset seen in the Western Region is primarily due to a low incidence of "older type" of breast cancer rather than an absolute excess of "younger type".

#### ACKNOWLEDGEMENTS

I am pleased to have this opportunity to express my gratitude to the many people and organisations who have helped me during the preparation of this thesis:

To King AbdulAziz University Jeddah and The Ministry of Higher Education who initiated The Joint Supervision Programme funded my studies and gave me leave of duty to participate in it. My thanks therefor to all those who involved in the programme, the staff of the Joint Supervision project past and present, and to the College of Medicine and Allied Sciences and my department, Medical Biology, who supported my application to join the programme. Thanks also must go to the administrative staff at Leicester University who dealt with what was a novel programme, and who were very helpful throughout my period of study.

Special thanks to my supervisor Dr Rosemary Walker, for her advice and constant support, and to Dr Zainy Banjar my local supervisor here in Jeddah. Appreciation also to the Departments of Clinical Biochemistry, Haematology, and The King Fahad Medical Research Centre and its Director Dr Zuhair M.H. Al-Mazouki, for giving me access to facilities. Appreciation also to Prof. Mohammed Al-Jerash for helping me get started on Windows 95, Excell and Minitab programmes.

Thanks to Mr AbduRahiman Pattani for technical assistance. Thanks also to Mrs Helen Khoja for compiling and typing my contents list and, with Mrs Poala Tashkandi and Miss Sumayah Felemban, transferring my references into a data base.

I am very grateful to the co-operation and help shown to me by hospitals in Jeddah who provided me microtome training, data, and samples, namely:

King AbdulAziz University Hospital, special thanks to Dr. Osamma Nassif, and Dr. Ibrahim Zahrani and staff and technicians of the Pathology department.

King Khalid National Guard Hospital, to Dr F.I.Joharjy the Director of Health Affairs (for the National Guard) Western region, and to the Pathology department especially to Dr Peter Coode, for his help and to Brian Gilpin for technical assistance.

Jeddah Military Hospital, to the staff of the pathology department especially Dr Adel Danish, and to Mr Mark Bronitt for technical assistance.

Erfan and Bagedao Hospital, the Director Dr Erfan and the Pathology Dept especially Dr S. Elderiny.

King AbdulAziz Red Sea Hospital, thanks to Prof. Omar for all his help and encouragement, and also to Mr Tunde and Mrs Dori for technical assistance. King AbdulaAziz Red Sea Hospital, Oncology Centre, Western Region Tumour Registry. Special thanks to Dr Assem Al-Radi the director of the National Cancer Registry for the Western and Northern Regions, and also to Dr Vijay, and Mr Riyadh for all their help and co-operation in giving me access to tumour registry data and so enabling me to compare local and international data in chapter 2, and Saudi And non-Saudi patients in chapter 3.

Thanks to the faculty and staff of the Pathology department at Leicester University, in particular Dr Peter Furness for writing me a macro, and bringing samples from Dr Walker, when visiting his Joint Supervision Student. Thanks also to Mrs Sheila Dearing for technical help particularly for preparing samples from Leicester, and to Malcolm Rae for dealing with urgent requests.

Finally, but not least, I must say thank you to my family for their constant help and support, and for tolerating me during this long period of study.

## CONTENTS

## CHAPTER ONE

**INTRODUCTION** 

Breast cancer is an important clinical problem world-wide, not only in countries like the UK, which have a high incidence of breast cancer, but also in countries with a much lower overall incidence such as Saudi Arabia. Breast cancer is attributable for 20% of all female malignancies in the UK (McPherson et al, 1994) and 18% of female malignancies in Saudi Arabia, (NCR 1996). The disease is very heterogeneous in terms of its epidemiology, incidence varying up to seven fold in different countries (Parkin et al, 1992), and also with regards to its biological and clinical course (Devilee et al, 1994). Publications from Saudi Arabia have assessed breast carcinoma as being aggressive and affecting a young age group (Al-Idrissi et al, 1992; Amr et al, 1995; Tandon et al, 1995; Ezzat et al, 1999) when compared with the west. Asian populations residing in the UK have also been found to have significantly lower rate of breast carcinoma, which affects a younger age group (Winter et al, 1999), and presents with more advanced disease (Potter et al, 1983). My study will comprise age matched populations of breast carcinoma patients from Saudi Arabia (Jeddah) and Asian and European breast carcinoma patients from the UK (Leicester).

In order to study the mechanisms by which a breast carcinoma achieves excessive, uncoordinated growth it is necessary to outline the basic structure, cell organisation, and control of cell division in normal breast tissue.

### **1.1 THE NORMAL BREAST**

#### **1.1.1 BASIC STRUCTURE**

The normal breast of a female of reproductive age is formed of segments each comprising 6-10 lobules containing several acini, linked by terminal ducts; this forms the terminal duct lobular unit (TDLU) (Fig1.1). The TDLUs are connected via a heirachy of ducts to the lactiferous ducts and sinuses, which open to the outside.

#### **Components of the breast**

*Acini:* The acini, the milk producing glands of the breast, are lined with cuboidal epithelial cells attached to a basal layer of myoepithelial cells which adjoin the basement membrane.

*Ducts:* The areolar, nipple and openings of the lactiferous ducts are covered with stratified squamous epithelium; further along the major ducts this changes to first pseudostratified colomnular epithelium, and then to double layer of cuboidal epithelium. Parallel to the ducts is a layer of myoepithelium (Stirling and Chandler, 1976). *Lobules*: The individual lobules are surrounded by dense collagenous inter lobular stroma, and all are further enclosed by a looser stroma, the intralobular connective tissue.

#### **1.1.2 NORMAL BREAST CHANGES**

Changes occur in the female breast associated with puberty, the menstrual cycle, pregnancy, lactation, and menopause.

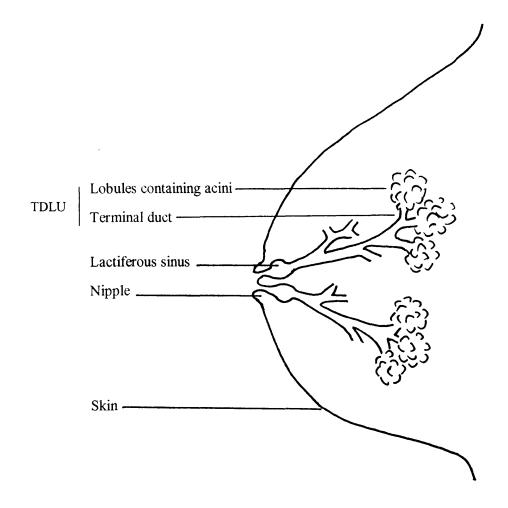

#### Puberty

Prior to puberty there are a few ducts present in the breast, but no acini. After the onset of menarche, for the first 1-2 years, oestrogen predominates over progesterone synthesis, and causes the ducts to elongate, branch, and to develop terminal buds (which will later form the acini). The amount of fat and connective tissue in the breast also increases. Growth of the breast continues until the mid 20's unless pushed to maturity earlier by the occurrence of a pregnancy. An international study for the World Health Organisation (Morabia and Costanza, 1998) found menarche to have median values varying between 13-16 years.

#### **Menstrual** Cycle

The breast undergoes cyclic changes, in synchrony with ovulation and menstruation (Longacre and Bartow, 1986) from menarche until menopause, unless interrupted by a pregnancy. Normal breast tissue therefore is not static in nature, but undergoes a cycle of proliferation and apoptosis, under hormonal regulation. (Table 1.1)

Adapted from: Walker RA Chp 16 The breast, General and systemic pathology Underwood JCE (Ed), Churchill Livingstone (pub) 1992 Cycles in which no ovulation occurs, anovulatory cycles, are not associated with the changes of hormone levels described. Many of the irregular cycles experienced by postmenarcheal girls are anovulatory (Vihko and Apter, 1984), strenuous physical exercise in this group may also lead to a decrease in the number of ovulatory cycles (Bernstein et al, 1987). In some women post partum cycles may either be absent or anovulatory during the months spent breast feeding.

| Day of cycle | Phase and hormone levels      | Events in Breast                        |
|--------------|-------------------------------|---|
| 14           | Ovulation                     | Cells of ducts and acini start to       |
|              | progressive rise in oestrogen | proliferate                             |
| 22 - 24      | Secretory phase influence of  | Terminal ducts: increase in             |
|              | progesterone                  | proliferation and structure.            |
|              |                               | Basal epithelial cells: increase in     |
|              |                               | mitotic activity, and vacuolisation     |
|              |                               | Stromal cells : proliferation and       |
|              |                               | stromal oedema                          |
| 28           | Menstruation                  | Epithelial cells: apoptosis             |
|              | fall in oestrogen and         | Intralobular connective tissue: atrophy |
|              | progesterone levels           | Stromal cells : reduction of oedema     |
|              |                               | Ducts and glands : shrinkage            |

| Table 1.1 | Breast changes duri | ng the menstrua | l cycle (Vogel et al, 1981) |
|-----------|---------------------|-----------------|-----------------------------|
|           |                     |                 |                             |

#### Pregnancy

Proliferative changes occur in the breast through out pregnancy in preparation for nursing, under hormonal control. (Table 1.2)

Table 1.2 Breast changes during pregnancy

| Hormone      | Stage of Pregnancy   | Function                                    |
|--------------|----------------------|---|
| Oestrogen    | 3-4 weeks            | Increase branching of ducts                 |
|              | 5-8 weeks            | Breast enlargement                          |
| Progesterone | 3-6 months           | Increase lobular formation.                 |
|              |                      | Acini produce colostrum causing an increase |
|              |                      | in the volume of the breast.                |
|              |                      | Cells are in a pre secretory state.         |
| Prolactin    | increases slowly     | Initiates protein synthesis in mammary      |
|              | throughout pregnancy | epithelium.                                 |

#### Lactation

Birth causes an abrupt withdrawal of the hormones oestrogen and progesterone which previously dampened the effect of prolactin on the mammary epithelium. Prolactin, insulin, and cortisol, cause the mammary epithelial cells to progress to the secretory state. The continued production of prolactin is stimulated by suckling, and when breast feeding ceases the prolactin levels drop and there is rapid involution of the glandular tissue and the breast returns to its resting state.

#### Menopause

Reduced ovarian function results in involution of the epithelial structures and stroma. In post menopausal women the breast becomes increasingly composed of adipose tissue as the other components shrink. Morabia and Costanza (1998) found little international variation in age at natural menopause, the mean age world wide being 50 years.

Normal breast tissue can therefore be seen to be in a state of dynamic change throughout the life of the female, controlled by the interaction of ovarian hormones, until the post menopausal phase.

#### **1.1.3 ORGANISATION OF EPITHELIAL TISSUE IN THE BREAST**

Epithelial tissue is an ordered, polarised, compact tissue (Fig 1.2). The overall organisation of epithelial tissue is maintained by:

a. Cell - cell interaction: Cells "recognise" each other and adhere to one another via molecules and receptors on their surface, and by linking junctions.

b. Cell - matrix interactions: Cells have an intimate contact with the molecules of the extracellular matrix (ECM).

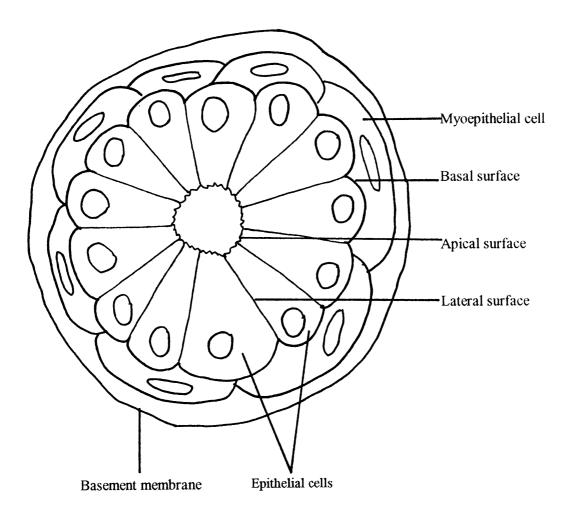

c.Extra-cellular differentiation and growth factors: Tissues require growth factors, differentiation factors and hormones to maintain them in a particular state.

#### The surface membrane of epithelial cells

The cells of epithelial tissues are highly polarised, the cell membrane of the top (apical) surface of the cell having a different composition of components than the membranes at the side (lateral membranes) or those at the bottom (basal membrane). *The apical membrane* 

Due to its molecular composition the apical surface has a negative charge, one of the effects of which is to repel other cells so that the apical surface is always the free surface of the tissue. The apical surface may also perform the specialised function of secretion (as occurs in the breast during lactation).

## Fig 1.2 Organisation of epithelial cells in acinus

Adapted from: Walker RA Chp 16 The breast, General and systemic pathology Underwood JCE (Ed), Churchill Livingstone (pub) 1992

#### The basal membrane

The basal membrane is attached to the basement membrane via cell matrix junctions e.g. focal contacts and integrin receptors (Birchmeier and Birchmeier, 1993). *The lateral membrane* 

The lateral membrane has many of the compounds found on the basal membrane and also some unique features e.g. gap junctions, adherence junctions. In addition there are cell adhesion molecules (CAMs) which hold the cells tightly and are important for cell-cell recognition.

#### **Cell adhesion molecules**

There are three main types of CAM:

#### 1.Cadherins:

Calcium dependant adhesion molecules are both receptor and ligand (Takeichi, 1990). All the cadherins are transmembrane proteins which tend to be at a greater density at cell junctions. There are at least three classes of cadherins in normal breast tissue: E-Cadherin, located in adult epithelial tissue E cadherin is both involved in the formation of adherence junctions and in signal transduction pathways (Ben-Ze'ev, 1997). H -cadherin, expressed predominantly in the heart, is also found in the epithelial tissue of the breast (Lee, 1996).

P-Cadherin, is found in the myoepithelial cells of the breast (Soler et al, 1999).2.Integrins:

Integrins are transmembrane cell adhesion molecules; each sub family of integrin receptors (Hynes, 1992) has a common  $\beta$ subunit interacting with a specific  $\alpha$ subunit. Binding to the ligand occurs by recognition of specific amino acid sequences found in several ECM proteins including laminin, and fibronectin (Ruoslahti and Pierschbacher, 1987). Integrins also interact with the cytoskeleton, and pass signals across the cell membrane and therefore have a role in the regulation of cell function. 3.Immunoglobin super family adhesion molecules:

Are also transmembrane molecules which includes VLA-4 which binds to VCAM-1 a ligand expressed by epithelial cells (Hemler et al, 1990).

In addition to its role in maintaining normal tissue structure, studies by Gadbois et al (1997) and Nigro et al (1997) demonstrate that loss of adhesion may result in the reduction of cell cycle check point controls.

#### The extracellular matrix

There are two types of extracellular matrix (ECM):

1. The basement membrane, a thin matrix which provides the foundation for epithelial cells, separates the tissue from the surrounding stroma and acts as a barrier controlling the passage of macromolecules and penetration by cells. The components of the basement membrane are in contact with the cells via receptors and cell adhesion molecules and are involved in the determination of the structure, polarity, and migration of the cells (Martinez-Hernandez and Amenta, 1983; Timpl and Dziadek, 1986; Birchmeier, 1993).

2. The interstitial connective tissue, found separating structures of the lobules of the breast.

The basement and interstitial connective tissue vary in organisation but are composed of similar components; collagens, glycoproteins, and proteoglycans. Adhesion to ECM molecules, via secondary signals, helps regulate cell division (Gadbois et al, 1997) and cell cycle checkpoint control via p53 (Nigro et al, 1997).

### **1.2 THE NORMAL CELL CYCLE**

The normal cell cycle is a continuous process composed of four stages: M phase : Mitosis : active cell division G<sub>1</sub>: gap phase one : cell prepares for DNA replication S phase : synthesis phase : DNA is duplicated to form bivalent chromosomes G<sub>2</sub>: gap phase two : cell prepares for cell division

Those cells which are not actively dividing may either be terminally differentiated and unable to re-enter the cell cycle, or may be in a state of rest  $(G_0)$ , not actively dividing but still capable of re-entering the cell cycle if subjected to the suitable stimulus.

#### **1.2.1 GENERAL PATHWAY OF INITIATION**

Normal breast tissue is regulated by an interaction of many hormones and growth factors. Growth factors bind to receptors on the surface of the cell, for example epidermal growth factor (EGF) binds to EGF receptors (EGFR) and activates them. After binding, some receptors have intrinsic protein tyrosine kinase activity such as EGFR. Receptors which do not have intrinsic protein tyrosine kinase activity activate intracellular protein kinases, which are proteins on or near the inner membrane, and pass the stimuli along to the secondary messengers which are phosphorylated proteins.

A series of secondary messengers pass the signal across the cytoplasm, it then crosses the nuclear membrane where transcription factors are activated and DNA synthesis occurs allowing the S phase of cell division. The steroid hormone receptors e.g. oestrogen, and progesterone receptors, are located within the nucleus, and are activated by binding of the respective hormone.

#### **1.2.2 CONTROL OF THE CELL CYCLE**

Growth factors stimulate the cell to progress from  $G_0$  to  $G_1$  and once stimulated the events of cell division are controlled by cyclins, proteins which then form complexes with the protein kinases CDKs. The cyclin/CDK complexes are then able to regulate cell division by phosphorylating the substrate proteins required during the cell cycle (Table 1.3). Once the cell has entered the cell cycle there are check point controls, including those between  $G_1$  - S, and  $G_2$  - M which function by ensuring that key events in the cycle have occurred correctly before mitosis can proceed. Cyclin dependant kinase inhibitor proteins (CKIs) bind to cyclin/CDK complexes and inhibit function thus stopping the cell cycle (Hartwell and Weinert, 1989) (Table 1.3).

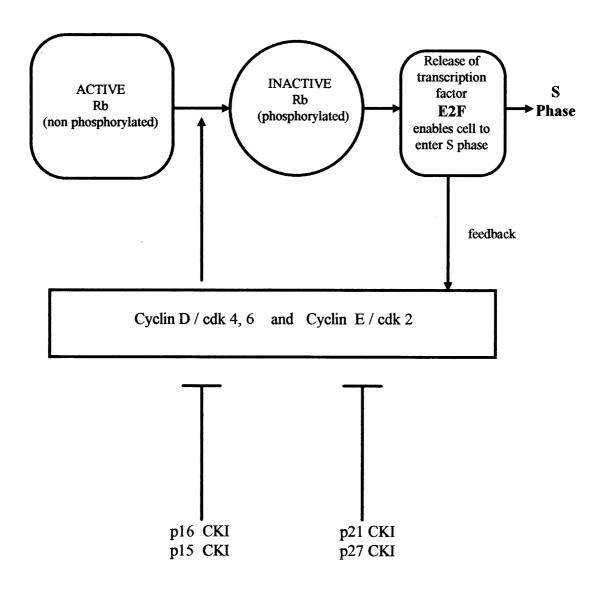

| stage of cell        | cyclin | associated | Function  | associated       |
|----------------------|--------|------------|---|------------------|
| cycle                |        | CDK        |   | СКІ              |
| Stage G <sub>1</sub> | D      | CDK4       | Control entry into S phase.                     | p16°             |
|                      |        | CDK6       | Initiate DNA replication.                       | p15 <sup>f</sup> |
|                      |        |            | The START checkpoint after which                |                  |
|                      |        |            | cells are committed to replication <sup>a</sup> | p27 <sup>g</sup> |
| late G <sub>1</sub>  | E      | CDK2       | Drives the cell through the $G_1/S$             | p27 <sup>g</sup> |
|                      |        |            | checkpoint <sup>b</sup>                         |                  |
| S Phase              |        | CDK2       | Starts S phase and ensures progression          | p21 <sup>h</sup> |
|                      |        |            | through to M <sup>c</sup>                       |                  |
| Stage G <sub>2</sub> | В      | CDK1       | Controls transition from $G_2$ to $M^d$         |                  |
|                      |        |            |   |                  |

| Table 1.3 Cyclin / | CDK ( | complexes | and i | interaction | with CKI's |
|--------------------|-------|-----------|-------|-------------|------------|
|--------------------|-------|-----------|-------|-------------|------------|

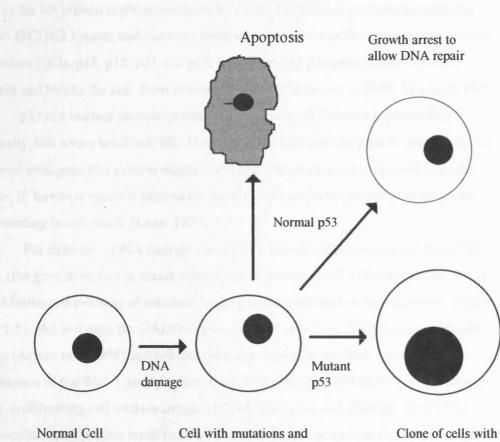

a:(Scheer, 1993) b:(Reznitsky et al, 1995) c:(Girad et al, 1991, Schulman et al, 1998) d:(Cardoso et al,1993) e:(Serrano et al, 1993) f:(Hannon and Beach, 1994) g:(Koff et al, 1993) h:(Dulic et al, 1994)

Rb, and P53 are proteins which interact with cyclin/CDK complexes and CKI's in many of the pathways controlling cell division and apoptosis (Figs 1.3 and 1.4). Apoptosis is genetically controlled single cell death (Kerr et al, 1972). It can occur as part of normal development, e.g. the regression of normal glandular breast tissue after

Adapted from Marshall (1999)

# Fig 1.4 p53 in apoptosis and cell cycle arrest

chromosomal aberrations

mutations and chromosomal aberrations and possible malignant potential

Adapted from Carson and Lois 1995

Rb when activated (underphosphorylated) stops the cell from making the transition from  $G_0$  or  $G_1$  to the S phase by binding transcription factors in the pocket region of the molecule. When the cells are subjected to stimulation (e.g. by a growth factor) the Rb protein is phosphorylated by cyclin D/CDK4, 6 and subsequently by cyclin E/CDK2 kinases and becomes inactive allowing the cells to progress to S phase. Therefore CKIs, p15, p16, p21 and p27, which prevent phosphorylation of the Rb protein and blocks the cell from entering S phase (Serrano et al, 1993; Marshall, 1999).

p53 is a nuclear phosphoprotein which, when cell division is proceeding normally, has a very brief half-life. However if the cell sustains genetic damage due to external mutagens p53 protein maybe stabilised, allowing arrest of the cell to enable repair, if however repair is impossible then the cell enters the pathway of apoptosis culminating in cell death (Lane, 1993).

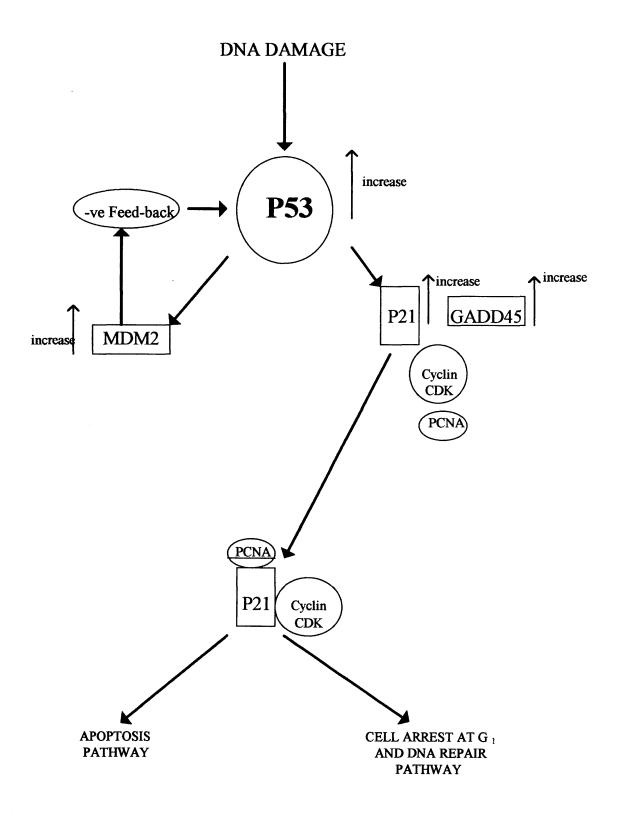

For example: DNA damage caused by ionising radiation activates the ATM gene (the gene defective in ataxia telangiectasia (section 1.4.3)) (Savitsky et al, 1995). ATM initiates a pathway of reactions leading to the stabilisation and activation of p53 (Fig 1.5). p53 activates the GADD45 gene (growth arrest and DNA damage inducible gene) (Artuso et al,1995) and induces the transcription of the Waf-1 gene and the production of the Waf-1 gene product, the CKI protein p21. GADD45 and p21interact with proliferating cell nuclear antigen (PCNA) (Sanchez and Elledge, 1995). The accumulated p53 protein binds to DNA and arrests the cell cycle at G<sub>1</sub> and p21 binds to the cyclin /CDK2 complex and stops the cycle progressing (Dulic et al, 1994), enabling DNA repair mechanisms to correct the damage caused by the mutagen. p53 also stimulates production of MDM2 which, by a negative feed back mechanism, limits the function of p53 by blocking its transcriptional activation domain (Oliner et al, 1993).

There is also p53 dependant regulation of the  $G_2/M$  checkpoint (Fig 1.6), two proposed mechanisms are:

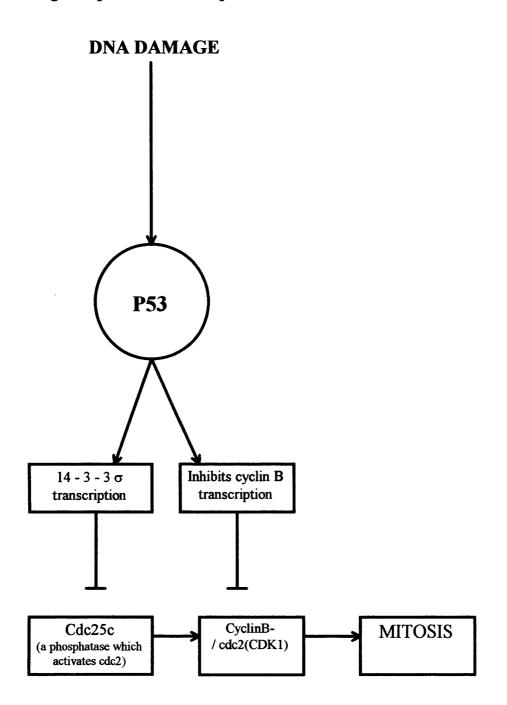

By decreasing intracellular levels of cyclin B1 and inhibiting cyclin B1 promoter activity (Innocente et al, 1999) since cyclin B1 is required for the  $G_2/M$  transition this mechanism blocks the cycle at  $G_2$ .

p53 dependant over expression of 14-3-3 $\sigma$ , a protein related to the Rad protein mitotic regulators in yeast, also effects an G<sub>2</sub> block (Hermeking et al, 1997). 14-3-3 $\sigma$  binds to the activator of cyclin B/CDK1 and blocks progression to M.

13

# Fig 1.5 p53 regulation of growth arrest and apoptosis at the G<sub>1</sub> checkpoint control

The above research on the p53 dependent check point was completed on ovarian and colorectal tumour cell lines and the relevance of either to breast has yet to be established.

P53 has also been implicated in the regulation of a mitotic spindle checkpoint (Cross et al, 1995), and may also induce growth suppression in neighbouring cells (Komarova et al, 1998). Due to its monitoring role and its involvement in many inhibitory pathways p53 has been named 'the guardian of the genome' (Lane, 1993). P53 can therefore be seen to have a central position in both the DNA repair and cell apoptosis pathways (Fig 1.4).

# **1.3 NEOPLASIA**

The process of neoplasia can be divided into two main stages: initiation and promotion.

# **1.3.1 INITIATION AND PROMOTION**

The cells of the human body are subjected to an almost continuous assault by potential initiating factors in particular carcinogens and UV radiation; and it is probable therefore that there will always be some initiated cells present. A few viruses have also been associated with the initiation of carcinogenesis in specific human tumours. E.g. Papillomavirus with carcinoma of the cervix, Epstein-Barr virus with Burkitts lymphoma, and Hepatitis B virus with hepatocellular carcinoma. An inherited genetic lesion may give cells of an individual a predisposition to develop tumours (Table 1.7) and act as an initiating step. Most of the genetic lesions in initiated cells are repaired by the cells repair mechanisms or where repair is impossible subjected to apoptosis as part of the normal cell cycle control (section 1.2.2).

Initiation is however is not sufficient on its own to produce tumours, a promotion factor is required to facilitate cell division of the initiated cell. Promotion factors could include growth factors and hormones, or mutation or loss of the genes responsible for the DNA repair mechanisms and induction of apoptosis would also facilitate the progression of the tumour. The theory of clonal expansion postulates that after exposure to the initiation factor and induction of cell proliferation by a promoting factor many different mutations occur and those cells having mutations which gives a proliferative advantage are selected for. This then becomes the dominant cell line (Nowell, 1976). Experimental evidence has demonstrated the clonal nature of many tumours (Fialkow, 1976; Nowell, 1976; Noguchi et al, 1992) which gives added credence to the theory of clonal expansion.

# **1.3.2 GENETIC CHANGES**

Karyotypic changes in neoplasia were described by Boveri (1914), and types of chromosomal aberrations found in neoplasms are outlined in Table 1.4. If a section of chromosome is deleted or duplicated the genes encoded by that section are lost or increased accordingly, and similarly if a translocation occurs the genes are also subjected to a new location possibly coming under new promoters or becoming non functional due to disruption of the coding sequences.

| Class      | Aberration    | Net change in<br>genetic material | Example   |
|------------|---------------|-----------------------------------|---|
| Numeric    | monosomy      | loss                              | monosomy chromosome 9   |
| Numeric    | polysomy      | gain                              | bladder carcinoma <sup>a</sup><br>trisomy chromosome 7<br>colon cancer <sup>b</sup> |
| Structural | deletion      | loss                              | retinoblastoma del(13q14) <sup>c</sup>  |
| Structural | amplification | gain                              | neuroblastoma dup(1 p31-32) <sup>d</sup>  |
| Structural | translocation | no net loss or gain               | chronic myeloid leukaemia<br>t(9;22) <sup>e</sup>                                   |
| Structural | Inversion     | no net loss or gain               | inv (16) Acute Myelo monocytic<br>leukaemia <sup>f</sup>                            |

Table 1.4 Types of chromosomal aberrations found in neoplasia

Refs: a:(Gibas et al, 1984) b:(Ochi et al, 1983) c:(Knudson, 1985) d:(Schwab et al, 1984) e:(de Klein et al, 1992) f:(Larson et al, 1986)

Two particular classes of gene are associated with neoplasia, oncogenes and tumour suppressor genes.

#### Oncogenes

Originally identified in transforming viruses, v-oncs, these genes are now realised to be genes found in the normal genome. Proto-oncogenes are genes required for the signal transduction cascade and cell division, but which when modified become oncogenic, c-oncs (Verma, 1986). The normal function of oncogenes is to respond to growth initiation signals and overexpression or deregulation can result in unregulated growth (Table 1.5).

Table 1.5Mechanisms of oncogene activation:

| Туре         | Mechanism                                | Example  |
|--------------|--|--|
| Structural   | Point mutation, resulting in a change in | Mode of activation                             |
| change       | gene product.                            | frequently seen in Ras <sup>a</sup>            |
| Structural   | Chromosomal translocation within         | Ph <sup>1</sup> chromosome in CML <sup>b</sup> |
| change       | coding regions giving rise to a fusion   | Abl:Bcr fusion gene                            |
|              | gene product.                            | product <sup>°</sup>                           |
| Deregulation | Chromosomal translocation: gene          | Burkitts Lymphoma                              |
|              | under the influence of a strong or       | t(8;14) <sup>d</sup>                           |
|              | constitutive promoter.                   |  |
| Deregulation | Amplification of gene: formation of      | Neuroblastoma                                  |
|              | homogeneously staining regions           | amplification of Nmyc <sup>e,f</sup>           |
|              | (HSRs) and double minutes (Dmins)        |  |

Refs: a:(McGrath et al, 1984) b:(Nowell and Hungerford, 1960) c:(Shtivelman et al, 1985) d:(Croce and Nowell, 1985) e:(Seeger et al, 1985) f:(Schwab, 1984)

Oncogenes can be classified into several "families" according to their position in the signal transduction cascade (Weinberg, 1989) see Table 1.6.

| Class                 | Example  | Action   |
|-----------------------|--|--|
| Growth factor         | c-sis  | βchain of platelet derived growth factor<br>(PDGF) <sup>a</sup>  |
| Receptor              | c-erb-B2   | overexpression of cerbB2 associated<br>with aggressive breast cancer <sup>b</sup>  |
| Signal<br>transducing | GTP binding<br>proteins e.g. Ras<br>non receptor<br>kinase c-abl | Ras is mutated and is constituatively active <sup>c</sup><br>translocation t(9;22) and the formation of the<br>abl:bcr fusion protein with increased kinase<br>activity <sup>d</sup> |
| Nuclear proteins      | Мус  | activated by amplification <sup>e</sup> and deregulation <sup>f</sup>  |
| Apoptosis             | Bcl-2  | over expression blocks apoptosis <sup>g</sup>  |

Table 1.6Oncogene families

#### **Tumour Suppressor Genes**

Another group of genes whose normal function is to respond to growth inhibitory signals causing the stoppage of the cell cycle or apoptosis (section 1.2.2) are the tumour suppressor genes (TSG).

Early cell fusion experiments (Harris et al, 1969) observed that the fusion of a normal cell with a tumour cell tended to result in the suppression of the malignant phenotype. From these observations it was apparent that some mutated genes causing the tumour were recessive to the normal wild type genes and that transformation and expression of the malignant phenotype appeared to be under separate genetic control (Stanbridge and Wilkinson, 1978).

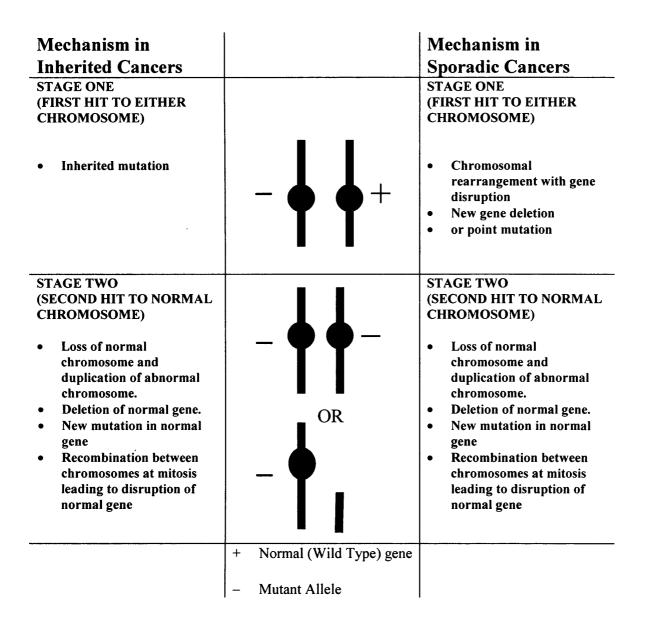

Knudson (1971), developed a two hit hypothesis for tumour development in retinoblastoma. Knudson's hypothesis postulated that in the familial form of the disease the child inherits a mutation present in the germline of one of the parents and only when a second somatic mutation occurs is the disease manifest, whereas in the sporadic form no mutation is inherited, and for the disease to occur two somatic mutations must arise in the developing retinal cells. This is generally known as the two-step or two-hit hypothesis (Fig1.7). The germline mutation anticipated in Knudson's early papers was later identified a deletion of q14 band on chromosome 13. Knudson used the term antioncogenes to describe this class of gene (Knudson, 1985), these are now called tumour suppressor genes (TSG). Some TSGs in inherited syndromes are listed in Table 1.7.

| Gene | Syndrome                | Effect of mutated gene   |
|------|-------------------------|--|
| p53  | Li-Fraumeni             | loss of G <sub>1</sub> / S checkpoint                            |
|      |                         | loss or reduction of p53 apoptosis pathway                       |
|      | (section 1.4.3)         | patients with Li-Fraumeni have an increased risk                 |
|      |                         | of developing neoplasms including breast                         |
|      |                         | carcinoma *  |
| Rb   | Familial Retinoblastoma | loss of $G_o - G_1 / S$ checkpoint <sup>b</sup>                  |
| WT   | Familial                | loss of normal cell growth repression function <sup>c</sup>      |
|      | Wilm's Tumour           |  |
| APC  | Familial adenomatous    | mutated gene product no longer has the ability                   |
|      | polyposis FAP           | to bind $\beta$ catenins and form adherens juctions <sup>d</sup> |

Table 1.7 Tumour Suppressors with known germline mutation

# Fig 1.7 Two hit hypothesis

Adapted from Kingston 1989

Some mutant tumour suppressor genes form a protein which binds to the normal gene product, as occurs with some mutant forms of p53, thus resulting in loss of function even though a wild type allele is present. This is known as dominant negative (Lane, 1994). The tumour suppressor genes shown in Table 1.7 also occur in non familial neoplasms. p53, in particular, has a central role in cell cycle control and DNA damage repair (Figs 1.4, 1.5 and 1.6) and somatic mutations of this gene are one of the most frequent in human cancer (Hollstein et al, 1991; Lane, 1994). Other genes involved in negatively regulating growth, inducing apoptosis, DNA repair, and maintaining tissue structure have also been identified as tumour suppressor genes or candidate tumour suppressor genes.

## Loss of heterozygosity

In persons with a constitutional karyotype heterozygous for a polymorphic satellite DNA marker, loss of heterozygosity, LOH, of that marker in the tumour reveals the possible position of a tumour suppressor gene closely linked to the marker. LOH is a frequent event in solid tumours indicating the role of tumour suppressor genes in the process of tumourigenesis in these tumours (Hansen and Cavenee, 1987). The term allelic imbalance (Devilee et al, 1991) may be used instead of LOH as being more inclusive, including both allelic change due to amplification as well as deletion of an allele (Chapter 4 section 4.1.1).

# **1.3.3 GENOMIC STABILITY**

Cells have several mechanisms for repairing mutations to the DNA and thus help maintain genomic stability (section 1.2.2). Many of the genes which control these pathways are tumour suppressor genes. If the function of these genes are lost then mechanisms for maintaining genomic stability are no longer present, mutations can occur unchecked and genetic instability may ensue, any mutation which causes an increase in the overall rate of mutation will also serve to accelerate the process of neoplastic progression.

#### **Defective DNA repair**

There are some rare autosomal recessive hereditary conditions which exhibit genomic instability due to DNA repair defects.

#### Bloom's syndrome:

The cells exhibit a high rate homologous recombination and of sister chromatid exchange, and patients are hypersensitive to a wide range of DNA damaging agents and have a predisposition to several types of cancer (German, 1972). It is a defect in the genes producing DNA ligase that is thought to contribute to this syndrome (Barnes

21

et al, 1992a). Some lines of Bloom syndrome cells have been found to be defective for a radiation induced increase in p53 expression which would normally result in apoptosis (van Laar et al, 1994).

## Fanconi's anaemia:

Patients are extremely sensitive to DNA x-linking agents, due to an absence of the enzymes which eliminate these cross linkages, and have a predisposition to develop leukaemia. There are apparently at least four pairs of genes involved in this disease (Strathdee et al, 1992). The pathway of p53 radiation induced apoptosis appears to be deficient in these patients (Rosselli et al, 1995).

#### Ataxia-telangiectasia (AT):

A genetically heterogeneous disease with at least six different molecular forms. Patients have a defective repair mechanism for dealing with radiation induced DNA damage, and are predisposed to develop lymphomas (Taylor, 1992). Individuals heterozygous for AT mutations have a 5-8-fold risk of developing breast cancer (Swift et al, 1987). (The role of AT gene and breast cancer is discussed in the section 1.4.3)

Individuals with these DNA repair deficiency syndromes are at an increased risk of developing tumours, and a study of the genes involved gives an insight to the role of genomic instability in neoplasia in general.

Defects in genes responsible for mismatch repair, *h*MSH2, *h*MLH1, *h*PMS1, *h*PMS2 have been correlated to microsatellite instability (MSI) in tumours (Bodmer et al, 1994; Nicolaides et al, 1994; Papadopoulos et al, 1994). Microsatellites are repetitive nucleotide sequences scattered through the genome, many of which exhibit individual specific length polymorphisms in normal tissue (Jeffreys et al, 1985). Variation in the number of repetitive sequences at a given locus has been observed in tumour tissue when compared with normal tissue from the same patient (Thein et al, 1987, Matsumura and Tarin, 1992). MSI is marked by expansion or contraction in the number of repeats in the tumour caused by slippage due to strand misalignment during DNA replication and was found in several studies on colorectal carcinoma. (Aaltonen et al, 1993; Thibodeau et al, 1993; Ionov et al, 1993), particularly in younger patients (<35 years) (Liu et al, 1995). MSI has also been recorded in other tumours including breast (Yee et al, 1994; Patel et al, 1994; Field et al, 1995; Watanabe et al, 1995; Shaw et al, 1996) and is reported as being more prevalent in post menopausal breast cancer patients (Fujii et al, 1998).

# 1.3.4 A MODEL OF GENETIC MECHANISMS INVOLVED IN THE PROCESS OF NEOPLASIA

Colorectal cancer has provided a model of the process of neoplasia in solid tissue, illustrating the multistep hypothesis of tumourigenesis. There are inherited syndromes which predispose individuals to develop colorectal adenomas and carcinomas and these have been useful in studying the genetic changes. (Table 1.8) The mutation of the APC (Adenomatosis polyposis coli) gene in FAP (Familial adenomatous polyposis), and the mismatch repair genes,  $hMSH_2$  and  $hMLH_1$ , in HNPCC (Hereditary non polyposis colon cancer) results in hyperproliferative epithelium. Further mutations in K Ras, deletion of DCC gene (deleted in colon cancer gene), and mutation or deletion of p53, cause the hyperproliferative state to become malignant (Fearon, 1992). The DNA in the malignant cells is now unstable and further mutations occur during the progression of the tumour.

| Inherited     | Early genetic              | Description                                      |
|---------------|----------------------------|--|
| syndrome      | changes                    |  |
| Familial      | Early LOH of               | Hundreds of diploid polyps of which only a small |
| adenomatous   | APC,                       | fraction develop to colorectal neoplasms         |

|-----------|--------------|-----------|--------------|----------------|------------|-----------|

a (Lynch et al, 1985) b (Liu et al, 1995)

The observations that FAP and GS, and similarly Lynch type I and type II, only vary from each other by the location of tumours suggests a mechanism responsible for tumour site specificity, the genetics of this mechanism however has yet to be fully explained. The process of mutation and selection is repeated resulting in the evolution of a neoplastic clone. An observation which supports this is that most adenomas appear to be monoclonal whereas the normal mucosa may have several separate cell lines (Fearon, 1992). Although there is a progression from normal to adenoma (if present) and then to carcinoma the precise sequence of genetic events may vary (Vogelstein et al, 1988), the total sum of events being more critical than the sequence (Fearon and Vogelstein, 1990). Colorectal carcinoma represents a progression from normal to benign and then to malignant, involving oncogenes, tumour suppressor genes and MSI and thus represents a model to which other tumours can be compared.

The characteristics which differentiate a benign neoplasm from a malignant neoplasm are its ability to invade surrounding tissue and to metastasise to distant sites.

# **1.3.5 INVASION AND METASTASIS**

Deregulated cell growth and subsequent clonal expansion gives rise to a mass of cells, a neoplasm, which may be either benign or malignant. The capability to invade surrounding tissue and therefore possibly spread to distant sites (metastasis) is the characteristic which classifies a neoplasm as being malignant, and which has no direct equivalent in normal breast tissue.

Angiogenesis, the microvascularization of the tumour is required if the tumour mass is to exceed 2-3mm in diameter (Ellis and Fidler, 1995). Blocking angiogenesis in mouse models significantly retards tumour growth (Hori et al, 1991). Angiogenesis also increases the risk of metastases (Weidner, 1992), tumours with no micro vascularization rarely invade the lymph or blood vessels (Liotta et al, 1976). The microvessels also secrete degradative enzymes which facilitate the extension of the vessels and their invasion by tumour cells (Rifkin et al, 1981).

During tumourigenesis there is breakdown of normal tissue organisation, and therefore, in epithelial tissue, of the interactions which keep cells attached to a basement membrane and maintain cells in a specific location. The genes for cell adhesion products, basement membrane components, and receptors may therefore be altered, deleted or their function negated resulting in or secondary to the process of invasion. Enzymes such as proteases may also be produced by the malignant cells, and the physical pressure exerted by the growing tumour may result in the breach of the basement membrane. Once this has occurred the process of invasion and possible subsequent metastasis can be said to have begun. Metastasis has three main phases firstly the invasion of the ECM, followed by vascular dissemination and then relocation and growth of tumour cells.

24

#### **Invasion of the ECM**

Initially there is a loss of cell : cell interaction. This is achieved by down regulation of the CAMs, in breast neoplasms particularly E-cadherin (Oka et al, 1993), and  $\alpha$  catenin (Rimm et al, 1995) as well as changes in  $\beta$  catenin molecules and plakoglobin (Sommers et al, 1994), which are involved in the functioning of E-cadherin. In breast carcinoma there appears to be a correlation between the density of laminin receptors and the invasiveness (Cioce et al, 1991) whereby loss of receptors can result in a loss of the normal relationship and encourage the ability to spread.

In addition to the mechanical pressure exerted by the growing neoplasm, there is enzymatic degradation of the ECM by proteases (Steeg, 1992). Migration of the tumour cells is stimulated by cytokines such as the autocrine motility factor, produced by the cell and activating receptors on the cell surface (Nabi et al, 1992). The proteinases then attack the basement membrane of the vessels allowing intravasation to occur.

## Vascular dissemination

Following intravasation the endothelial cells of the vessel release E-selectin, a carbohydrate binding compound which attracts T-lymphocytes to the site (Lasky, 1992). Once in the circulation neoplastic cells interact with the lymphocytes, and in the blood also with platelets, to form an emboli.

## Relocation at a distant site : Soil and seed theory

The formation of emboli may assist the neoplastic cells in relocating since the lymphocytes express L-selectin on their surface which initiates the adherence of leucocytes to vascular endothelium (Ley et al, 1991). Although the metastatic site is to a certain extent governed by the path taken by the emboli, neoplasms have a tendency to be site specific in the establishment of metastases dependant on the location of the primary neoplasm. For example most breast neoplasms tend to metastasise to bone, lungs, liver or brain, this tendency is described by the Soil and Seed Theory (Paget, 1889). The migration to specific sites could be influenced by :

i. Growth factors or hormones produced by the target organ.

ii. The types of CAM's receptors on the surface of the neoplastic cells.

iii. Locations may produce inhibitors which prevent growth of a specific neoplastic cell type (Rusciano and Burger, 1992).

It is however evident that the control of invasion and metastases has many interacting components and is therefore probably not attributable to any single gene. The neoplastic cell is under severe selective pressure during the process of metastasis and very few cells released into the circulation will actually reach the target organ and become established (Yosida, 1983).

# **1.4 BREAST CANCER**

There are many different parameters which may be measured to indicate the probable course of breast cancer. Prediction of behaviour has been assessed using clinical, pathological, and biological features.

# 1.4.1 CLINICO-PATHOLOGICAL ASSESSMENT

Breast cancer can be assessed clinico-pathologically according to its stage, histological type and grade:

# Stage

The stage defines the extent of spread of the disease. Most of the commonly used staging systems are modifications of the 1989 Pathologic classification of the UICC-AJC(Union Internationale Contre Cancer-American Joint Committee) (American Joint Committee on Cancer 1989). The TNM (Table 1.9) system stages tumours according to size of primary tumour, extent of regional lymph node involvement, and presence of distant metastasis, the stage in the TNM system being defined by the three letters with the appropriate subscripted number.

| Symbol | Description  |  |
|--------|--|--|
| Т      | Tumour size;                                       |  |
|        | ranging from $T_0 < 20$ mm to $T_4 > 100$ mm       |  |
| N      | Node status  |  |
|        | $N_0$ Node negative                                |  |
|        | N <sub>1</sub> Axillary node positive, mobile      |  |
|        | N <sub>2</sub> Axillary node positive, fixed nodes |  |
|        | N <sub>3</sub> Supraventricula nodes positive      |  |
| М      | M <sub>0</sub> No distant metastases               |  |
|        | M <sub>1</sub> Distant metastases                  |  |

Table 1.9T N MSystem

Stage may also be numbered I-IV according to clinical findings as described in Table 1.10.

Table 1.10 International Classification of Stage

| Stage | Description                    | Equivalent TNM stages <sup>a</sup> |
|-------|--------------------------------|------------------------------------|
|       | Breast lump, lymph nodes       |                                    |
| Ι     | not involved, slightly         | T1N0M0.                            |
|       | attached to the skin           |                                    |
|       | Breast lump, lymph node        | TON1MO,                            |
| п     | involvement, or attached to    | T1N1M0,T2N0M0,                     |
|       | the skin                       | T2N1M0, T3N1M0.                    |
|       | Neoplasm extensively           | T0N2M0,                            |
| ш     | attached to the skin, or fixed | T1N2M0,T2N2M0,                     |
|       | lymph nodes                    | T3N1M0, T3N2M0,                    |
|       |                                | T4NnM0, TnN3M0                     |
|       | Presence of distant            |                                    |
| IV    | metastases                     | TnNnM1                             |

n = any number a : American Joint Committee on Cancer 1989

The individual components of the TNM system are correlated to patient prognosis. Tumour size and axillary lymph node involvement are independent prognostic indicators (Carter et al, 1989). Patient prognosis is inversely related to the number of positive axillary lymph nodes (Ferguson et al, 1982). Tumour size is directly related to the probability of metastasis (Koscielny et al, 1984) the presence of which is a sign of advanced systemic disease, patients with tumours less than 1cm generally having a significantly better survival rate than patients with tumours bigger than 2cm (Peer et al, 1996).

# **Histological Type**

Breast neoplasms can either be in situ or invasive, giving two basic sub-divisions of classification. These are further divided up according to histological appearance and grade (Table 1.11).

In situ ductal carcinomas (DCIS) are confined within the basement membrane although have the potential to invade (Silverstein et al, 1987). Patients with DCIS have a better prognosis than patients with invasive carcinomas. Lobular carcinoma in situ is considered to be an "at risk" lesion. There are several different identifiable histological patterns of DCIS (Table 1.11). High grade comedo type tumours appear to be more aggressive and associated with a higher rate of recurrence (Lagios et al, 1989; Patchefsky et al 1989) and hence poorer outcome than low grade non comedo type tumours.

Invasive carcinomas can be divided into specialised types and non-specialised. Infiltrating ductal carcinoma not otherwise specified is the most frequent type. Of the specialised types tubular carcinomas are well organised and are associated with a favourable prognosis (Carstens et al, 1985). Medullary carcinoma, a relatively uncommon tumour, also has a favourable prognosis (Rosen et al, 1982) and a low frequency of axillary lymph node involvement (Wargotz and Silverberg, 1988). Two other uncommon variants, mucinous (Rasmussen et al, 1985) and invasive papillary carcinoma (Fisher et al, 1980) are both associated with a favourable prognosis and low rate of recurrence. The knowledge that a patient has a tumour with a favourable prognosis aids in the selection of post-surgical treatment.

|                | Location/Description  |  |
|----------------|---|--|
| Insitu         | ductal carcinoma in situ, (DCIS)                                |  |
| (non invasive) | in situ tumours are graded high, intermediate and low           |  |
|                | formally described by histological architecture into            |  |
|                | comedo, and non-comedo  |  |
|                | non comedo comprising of other histological patterns such as    |  |
|                | cribriform, micropapillary, papillary, solid.                   |  |
|                |   |  |
|                | lobular carcinoma in situ,(LCIS)                                |  |
| Invasive       | Infiltrating ductal carcinoma (IDC)                             |  |
|                | not otherwise specified (NOS)                                   |  |
|                | and specialised types with characteristic histological patterns |  |
|                | medullary, mucinous,  |  |
|                | invasive papillary, and tubular                                 |  |
|                | Infiltrating lobular carcinoma (ILC)                            |  |

 Table 1.11
 General classification of breast neoplasms

The prognosis for patients with ILC depends on stage at presentation and on the histological sub-type (Dixon et al, 1982). The diagnosis of ILC is clinically relevant however because ILC can be multicentric and 25% of patients will develop a tumour in the contralateral breast (Richter et al, 1967; Lesser et al, 1982). Metastases from IDC tend to occur in the liver, bones, and parenchyma of the brain, whereas ILC has a predisposition to metastasise to the abdominal cavity and gastrointestinal tract (Harris et al, 1984), the ovaries and uterus (Kumar and Hart, 1982), and the meninges of the brain (Smith et al, 1985).

# Grade

The grade of a neoplasm is a measurement of the extent of which the cells have deviated from the normal. Two main approaches have been used to assess grade, dependant either on nuclear characteristics, or a combination of nuclear, cytological, and structural characteristics. The most widely used system is the modified Bloom and Richardson (Elston and Ellis, 1991) (Table 1.12) which uses a combined approach. Points are allocated for tubule formation, nuclear pleomorphism, and mitotic activity (Fig 1.8).

| Grade | Score | Degree of           |  |
|-------|-------|---------------------|--|
|       |       | differentiation     |  |
| I     | 3 -5  | well differentiated |  |
| П     | 6-7   | moderate            |  |
| Ш     | 8-9   | poor                |  |

Table1.12 : Modified Bloom and Richardson grading system

The Bloom and Richardson method of grading has been shown to be prognostically significant (Elston and Ellis, 1991).

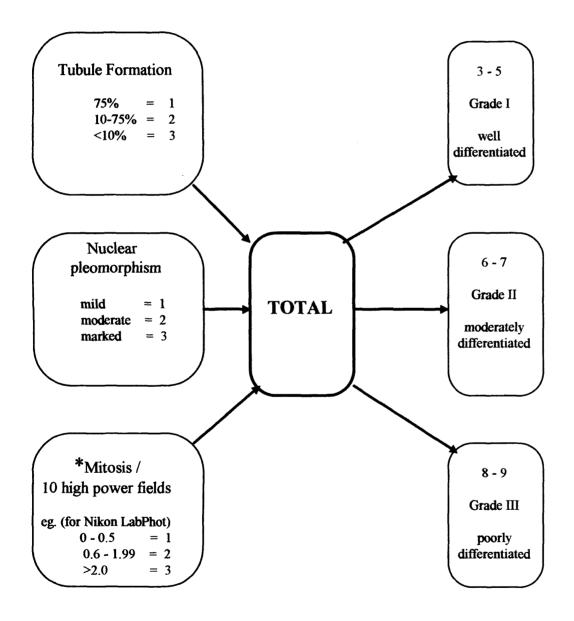

#### **1.4.2 BIOLOGICAL MARKERS**

Biological markers which prove to have clinical significance can provide information about aetiology, assess the probability and possible location of recurrence, and indicate the general prognosis. Some tumour markers may also indicate which treatment is most suitable for the patient.

# **Steroid Receptors**

Much of the normal functioning and development of the breast is controlled by hormones especially oestrogen and progesterone (Forsyth, 1991) (section 1.1.2), and hormones also have an important role in breast neoplasms. It is only in the presence of an appropriate receptor, that a hormone can induce a response in the cell.

# Fig 1.8 Histological grading (modified Bloom and Richardson)

#### Oestrogen receptor

The oestrogen receptor, ER, is a nuclear protein which has both hormonal and DNA binding domains (Kumar et al, 1986) which are both necessary for normal functioning. (Beato, 1989). In the normal breast ER changes with the menstrual cycle and with age. ER can be found in 60-70% of breast neoplasms, and is more frequently found in better differentiated carcinomas (Walker and Varley, 1993). The percentage of ER+ve tumours increases with age (Nicholson et al, 1995), and is a useful marker for potential response to endocrine therapy. With the identification of a second oestrogen receptor, ER  $\beta$  (Enmark et al, 1997) this is now known as ER  $\alpha$ .

## Progesterone receptor

The progesterone receptor, PgR, is regulated by oestrogen via the ER. Therefore the majority of neoplasms are either ER+ve/PgR+ve or ER-ve/PgR-ve, there are however some which are ER-ve/Pgr+ve (Clark and McGuire, 1989) The absence of PgR in breast neoplasms may be due to either defects in ER or it the PgR itself. LOH has been recorded about the PgR locus, but does not appear to correlate to loss of expression of the PgR (Walker and Varley, 1993).

Presence or absence of ER and PgR is clinically significant and allows deductions to be made as to the probable course of the disease and response to treatment. Tumours with a high concentration of ER and PgR are more likely to respond to endocrine treatment (Voogd et al, 1998; Castagnetta et al, 1999). There also is a variation in the probable site of metastasis; ER+ve tumours tend to metastasise to bone, whereas ER-ve tumours tend to metastasise to organs such as the brain, and liver (Campbell et al, 1981). Generally speaking ER+ve tumours are correlated with favourable characteristics (e.g. low grade), and hence ER+ve patients tend to have a more favourable prognosis (Blamey et al, 1980).

## **Growth Factor Receptors**

Epidermal growth factor receptor, EGFR, and epidermal growth factor, EGF, are both present in normal epithelial tissue. Approximately 40% of primary breast carcinomas over express EGFR (Sainsbury et al, 1987; Rios et al, 1988) and the overexpression has been found in many studies to be associated with aggressive tumours and poorer prognosis (Koenders et al, 1993).

#### **Cell Proliferation**

In addition to the mitotic index described as part of the grading system there are other markers of cell proliferation which appear to add relevant information to patient prognosis.

The proportion of cells in S-phase represents those cells which are actively dividing (section normal cell division). As might be predicted rapidly dividing cells respond better to chemotherapy, and it has been observed that the proportion of cells in S-phase is positively correlated to the response achieved during chemotherapy (Remvikos et al, 1989).

# Angiogenesis

The process of angiogenesis gives rise to microvascularization of the tumour, (section 1.3.5). Microvascular density has been demonstrated to have an inverse relationship to patient prognosis in both lymph node positive and lymph node negative patients (Weidner et al, 1992). Increased density also correlates to an increased risk of metastases (Toi et al, 1993). Gasparini et al (1994) finding microvascularization an independent prognostic factor in node negative and Viens et al (1999) in node positive patients. A few studies however have failed to find correlation (Hall et al, 1992; Goulding et al, 1995); this could be due to different detection techniques, or it could reflect the heterogeneity of breast carcinoma.

# 1.4.3 GENETICS OF BREAST CARCINOMA

A family history of breast neoplasia is known to increase a womans risk of developing the disease, especially at an early age (Houlston, 1992), and possibly accounts for up to 9% of all breast neoplasms (Lynch et al, 1989). Often such families also show a high rate of bilateral breast carcinoma (Thompson et al, 1994).

# Predisposing genes in familial breast cancer

#### BRCA1 and BRCA2

BRCA1 was localised on chromosome 17q21 by linkage analysis of families with early onset breast cancer (Hall et al, 1990). BRCA1 was cloned and more than 40 mutations identified in the early onset breast cancer families (Miki et al, 1994; Simard et al, 1994; Castilla et al, 1994). However, although BRCA1 has been found, it is very difficult to use for screening purposes to identify those at risk for familial breast and ovarian carcinoma, because of the large number of mutations and the size of the BRCA1 gene, over 100 kilobases long (Futreal et al, 1994; Miki et al, 1994).

BRCA2 was identified in familial breast cancer families which contained at least one affected male (Stratton et al, 1994) and located on chromosome 13q12-13 (Wooster et al, 1994). Together BRCA1 and BRCA2 account for the majority of familial breast carcinomas.

#### Li-Fraumeni Syndrome and p53

Patients with Li-Fraumeni syndrome have a germline mutation of p53 (Malkin et al, 1990). In a few families no mutation has been identified (Santibanez-Koreg et al, 1991); recently Bell et al (1999) showed that some of these families have germline mutations of the gene hCHK2, a homologue of the yeast Rad  $G_2$  checkpoint control genes. The Li-Fraumeni syndrome is autosomal dominant, and families with this syndrome develop malignancies at a young age (Li and Fraumeni, 1969). The malignancies often occur during childhood and include sarcomas, adrenal cortical carcinomas, osteosarcomas, acute leukaemia, and brain tumours. The mothers of these children are at risk of developing breast carcinoma, approximately half the women with such a mutation will develop breast cancer (Narod, 1994). The loss of function of p53 has also been shown to result in increased genomic instability in Li-Fraumeni cells (Liu et al, 1996).

## Genes predisposing to sporadic breast cancer

# BRCA1, BRCA2 and p53

It has been proposed that BRCA1 and BRCA2 act as tumour suppressor genes in familial breast cancer, but it is not clear if they have the same function in sporadic breast cancer (Yang and Lippman, 1999). Reduced expression of BRCA1 has been shown to correlate to high grade (Wilson et al, 1999) and to predict the occurrence of distant metastases (Seery et al, 1999). Over expression of BRCA2 has been correlated to high grade in sporadic breast cancer (Bieche et al, 1999) LOH BRCA1 has been identified in 21-49% and BRCA2 in 30-38% of breast tumours (Beckmann et al, 1996). However somatic mutations have only rarely been identified for BRCA1 (Langston et al, 1996) and BRCA2 (Lancaster et al, 1996; Miki et al, 1996). Somatic mutations in p53 are very common in breast cancer and other cancers (Harris and Hollstein, 1993) and have been associated with an increase in genotypic instability (Eyfjord et al, 1995).

# Ataxia telangiectasia

In addition to the genes involved in familial breast cancer, the gene for human ataxia telangiectasia, ATM, may also be involved in breast cancer. Persons heterozygous for ataxia telangiectasia have a predisposition to develop breast carcinoma (section 1.3.3) increasing the risk of breast neoplasm five fold (Swift et al, 1991) approximately 1.2% of the population are heterozygous for AT (Pippard et al, 1988) and this could account for 7% of breast carcinoma (Easton et al, 1993). The AT gene although only increasing risk slightly has an additive effect due to the relatively high gene frequency. Deficiency in DNA repair, and the resulting genomic instability, may be a predisposing factor for developing forms of sporadic breast carcinoma (Parshad et al, 1996).

## Genetic alterations in sporadic breast cancer

## **Oncogene** amplification

Amplification and increased expression of *ERBB2* occurs in about 20 % of invasive breast carcinomas (Van de Vijver and Nusse, 1991). However c-erb-B2 expression in DCIS has been identified in 60% of DCIS of high grade type, indicating that it is an early alteration within a subset of cancers (Barnes et al, 1992b). Increased expression of the oncogene *ERBB2* have been correlated to adverse factors associated with poorer prognosis (Cline et al, 1987; Walker et al, 1989; dePotter et al, 1990).

MYC amplification and increased expression occurs in about 20% of breast carcinoma (Mariani-Constantini et al, 1988) and has been associated with post menopausal breast carcinoma (Escot et al, 1986). Alterations in the MYC gene have been associated with aggressive tumours (Garcia et al, 1989) and poor prognosis (Varley et al, 1987), especially in less well differentiated tumours (Adnane et al, 1989).

# Karyotypic changes

Involvement of chromosome arm 16q has been noticed to occur primarily in near diploid neoplasms and therefore may be an early event (Hainsworth et al, 1991), deletions in 3p have also been reported (Pandis et al, 1993). Of the few insitu neoplasms karyotyped, most were in the diploid range, showed less complex karyotypes than the more infiltrating cases, and several contained changes in chromosomes 1 and 16 (Pandis et al, 1992; Neilsen et al, 1989).

# Loss of heterozygosity

LOH has been found has been found to varying degrees for all the chromosomes but at rates higher than 35% for chromosome arms 6q and 17q and above 50% for 16q and 17p (Devilee and Cornelisse, 1994). Chromosome arm 17p shows LOH in up to 60% of breast carcinomas, many of which have somatic mutations of p53 (Varley et al, 1991). The topic of loss of heterozygosity and tumour suppressor genes in breast carcinoma is discussed further in chapter 4.

34

# 1.4.4 MODELS FOR THE DEVELOPMENT OF BREAST CARCINOMA

Although less evidence exists than for the colorectal carcinoma model (section

1.3.4), a model has been proposed for breast carcinoma.

Evidence for this model is derived from:

i. Retrospective histopathological data

ii. Biological data of changes in e.g. ERBB2 and ER.

A study by Devilee et al (1994) (Fig 1.9) describes the theoretical "normal" stem cells going to a predisposed dividing state, and then giving rise to

a. Atypical Ductal Hyperplasia ADH

b. DCIS

c. IDC

all of this being at a sub clinical level.

Further growth and clonal expansion of DCIS and/or IDC would result in clinical manifestations of the disease and continuing neoplastic progression.

Currently it is not possible to identify either stem cells or "premalignant" cells in normal or non-malignant breast. Observations exist however that help support some of the other steps in the model:

# ADH to IDC and DCIS

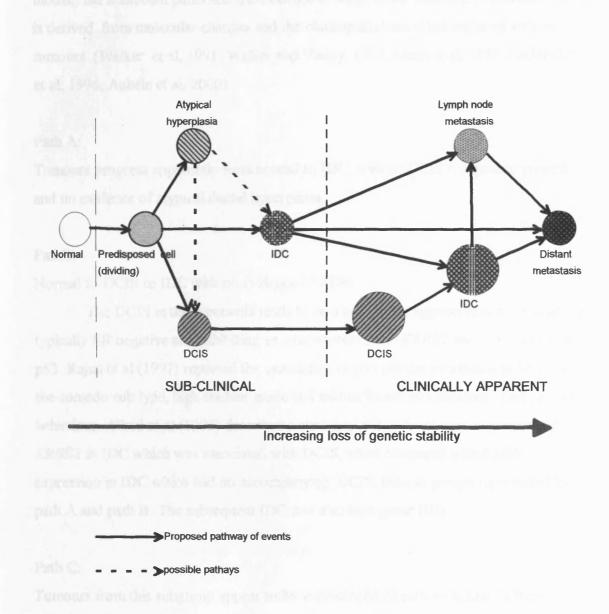

Atypical ductal hyperplasia, ADH, is a proliferative lesion which has some but not all the features of DCIS (NHSBSP Pathology Reporting Guidelines 2<sup>nd</sup> Edition 1995). Evidence for it being a precursor lesion comes from the following studies: i. Women with ADH identified in a previous biopsy have a 4-5 fold increase in the risk of developing breast cancer (Dupont and Page, 1985).

ii. ADH is monoclonal in nature (Noguchi et al, 1994; Lakhani et al, 1995)

iii. Molecular changes have been identified in ADH which also occur in DCIS (Lakhani et al, 1995; Chuaqui et al, 1997; Amari et al, 1999).

# DCIS to IDC

Knowledge of the natural history of untreated DCIS in human breast carcinoma is limited because it is normally removed once diagnosed. However, long term follow up of women who were originally diagnosed as having a benign lesion and only had a biopsy, who in fact had low grade DCIS, has shown that 10 of 28 women developed breast cancer, mainly invasive, after 24 years (Page et al, 1995). High grade DCIS have a higher rate of invasion (Lagios et al, 1989), if not excised.

# Fig 1.9 Development of breast cancer, Devilee model

Adapted from Devilee et al 1994

With developments in molecular studies the above model has been extended (Walker, 1997; Lakhani, 1999). Walker (Fig 1.10) describes three alternate pathways for the development of invasive breast carcinoma, each pathway having different characteristics. The relationship between ADH, DCIS and IDC, as well as that between DCIS and IDC derived from retrospective histopathological data form part of the model, the additional paths and the evidence to support the existence of alternate routes is derived from molecular changes and the clinicopathological behaviour of various tumours (Walker et al, 1991; Walker and Varley, 1993; Munn et al, 1995; Gretarsdottir et al, 1996; Aubele et al, 2000).

#### Path A:

Tumours progress apparently from normal to IDC, with no DCIS component present, and no evidence of atypical ductal hyperplasia.

#### PathB:

## Normal to DCIS to IDC with no evidence of ADH

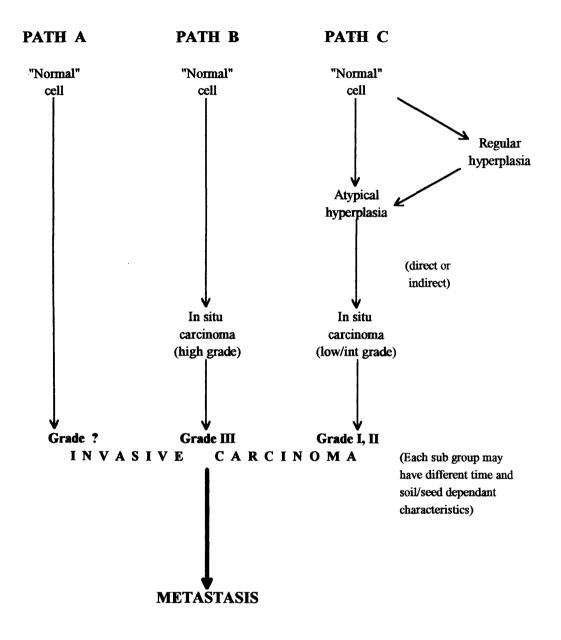

The DCIS in these patients tends to be a high grade aggressive tumour with cells typically ER negative and exhibiting an over expression of *ERBB2* and or mutation of p53. Rajan et al (1997) reported the association of p53 protein expression in DCIS with the comedo sub type, high nuclear grade and mitotic index, all indicators of aggressive behaviour. Allred et al (1992) described a statistically significant over expression of *ERBB2* in IDC which was associated with DCIS, when compared with *ERBB2* expression in IDC which had no accompanying DCIS, the sub groups represented by path A and path B. The subsequent IDC was also high grade (III).

## Path C:

Tumours from this subgroup appear to have developed directly or indirectly from atypical ductal hyperplasia. The DCIS tends to be low/intermediate grade and less aggressive than that seen in path B, cells are typically ER positive with no overexpression of *ERBB2*. IDC arising in this subgroup are also better differentiated and less aggressive and subsequently are of a lower grade (I,II).

The different pathways discussed in this model may help account for the heterogeneous nature of breast cancer, in which variation is seen in rate and length of time for recurrence to occur, site of metastasis, aggressiveness of the disease etc.

# Fig 1.10 Development of breast cancer, Walker modification

resulting in differing courses of disease. A recent study by Buerger et al (1999a) also suggested the existence of several distinct genetic pathways in the evolution of IDC associated with different tumour subtypes, and provided added evidence that DCIS is a direct precursor lesion of IDC. By understanding the apparent sub groups of breast carcinoma better it should be possible to better tailor treatment to patient needs.

# **1.5 AIMS OF THESIS**

My hypothesis is that breast cancer occurring in different ethnic groups differs in relation to incidence, age of onset, age specific pattern of incidence and aggressiveness. To test this I will investigate:

- Whether any differences observed in the age of presentation and incidence of breast cancer in the study populations reflects differences between low and high breast cancer incidences populations world wide.
- Whether breast cancer in Saudi Arabia and in the Asian community in Leicester occurs in a younger age group and whether it is pathobiologically and or genetically different from that found in the European Leicester breast cancer population.

Chapter Two will analyse age specific incidence rates (ASIR) in the study populations and in populations of high and low incidence of breast cancer. This analysis will attempt to ascertain whether any differences in age distribution can be attributed to possible differences in breast carcinoma or is merely an artefact of the population structure. The relative frequency of breast cancer at different ages and in different ethnic groups, when compared with the incidence of cancer at all sites will also be examined.

Chapter Three will compare nuclear morphometry and histopathological characteristics of breast tumours in the study populations for possible differences in features relating to aggression.

Chapter Four will compare the incidence of genetic alterations at selected chromosomal regions in breast cancers from the different study populations.

Chapter Five will summarise and discuss the results in relation to the different ethnic groups, and possible practical implications arising from these results. Ideas for future work will also be outlined.

# CHAPTER TWO

# AGE AND ETHNIC DISTRIBUTION OF BREAST CANCER

# **2.1 INTRODUCTION**

Several papers have commented that breast cancer occurs at a lower level of incidence, and at an earlier age, in Saudi Arabia than in the West and yet is still the most common neoplasm effecting women (section 2.1.5). Most of the ethnic differences in cancer incidence have been attributed to environmental risk factors as illustrated by the observations of Haenszel and Kurihara (1968) on the breast cancer incidence among Japanese immigrants to America and more recently among immigrants to Australia and Canada (Kliewer and Smith, 1995). The pattern of age specific incidence rates (ASIR the average annual incidence per 100,000 of the population in specified age groups) of breast cancer also vary between ethnic groups, but these differences have been largely attributed to cohort effects (Moolgavkar et al, 1979; Tarone and Chu, 1992; Winter et al, 1999). However the variation of an individuals genetic ability to cope with exposure to environmental risk factors may contribute to the observed differences, both individual and ethnic, in susceptibility to develop cancer (Feigelson et al, 1996; Neuhausen et al, 1999).

# 2.1.1 ENVIRONMENTAL RISK FACTORS INFLUENCING THE INCIDENCE OF BREAST CANCER

Environmental factors which appear to change the overall risk of tumourigenesis include both diet and reproductive behaviour. Normal breast develops and functions under the ebb and flow of oestrogen (section 1.1.2, tables 1.1 and 1.2). Environmental factors which expose the breast to oestrogen have been suspected to increase the risk of developing breast cancer and include both exogenous and endogenous sources.

#### Exogenous sources of oestrogen exposure

#### Oral Contraceptives

The major source of exogenous oestrogen is oral contraceptive (OC) use. Findings regarding increased risk have been both negative (Stadel et al, 1985; Beral et al, 1999) and positive (UK National case control study group 1989). The risk appears to be negligible with modern OC, although those who have a history of long term oral contraceptive use, especially before their first full term pregnancy (McPherson et al, 1987; Brinton et al, 1995a; Woodman, 1999) may be at a small additional risk. *Hormone replacement therapy* 

In addition to its use in OC oestrogen is also used in hormone replacement therapy, HRT, during the menopause. There is an apparent greater risk with increased time of oestrogen use (Briton et al, 1986; Gottlieb, 1999), this risk being higher for those that have been diagnosed as having benign breast disease (Thomas et al, 1982). There has been some debate recently about the nature of tumours arising in the breast after HRT, some reporting them to be less aggressive (Mayer, 1999) but others disagreeing (Stallard et al, 2000). Overall the benefits of hormone replacement therapy probably override any possible increased risk of breast carcinoma (Henderson et al, 1988; Shoup, 1999).

#### **Endogenous Sources of Oestrogen Exposure**

#### Reproductive factors

Early menarche, late menopause, and few or no pregnancies all increase the body's exposure to oestrogen, resulting in a woman with 40 years of menstruation having twice the risk of developing breast cancer as a woman with only 30 years (Trichopoulos et al, 1972). Since physical activity has been shown to delay menarche, physical activity in the pre-menarche period may reduce the individuals risk of breast cancer (Colditz and Frazier, 1995; Mittendorf et al, 1995).

Generally pregnancy is believed to increase the short term risk by stimulating cell growth but has an overall protective effect on permanent structural changes (Adami et al, 1995). Early pregnancy (before the age of 20) halves the risk of a nulliparous woman (MacMahon et al, 1970) and parity higher than 5 may also add a small additional amount of protection (Yuan et al, 1988). Lactation has been found to have a beneficial effect on breast carcinoma risk only if there is a long cumulative total period of breast feeding. Estimates have been made of a 30% reduction in risk for every five years total of breast feeding (Yuan et al, 1988). The effect is greatest when breast feeding starts below 22 years of age (Brinton et al, 1995b), breast feeding delaying or preventing ovulation, at least in some women.

However a comparison of menstrual and reproductive records in a group of American Asians (Chinese, Japanese, and Filipino), and American Caucasians concluded that the differences observed were not sufficient to explain the lower rates of breast cancer in the American Asian community (Wu et al, 1996a). *Obesity* 

It has been proposed that high total calorific intake, resulting in obesity, may be related to breast cancer incidence, rather the amount of one particular food type (Rao, 1996). The increased amount of adipose tissue in the body (increased body weight) results in more oestrogen being produced. Studies have revealed that excess weight over the age of 60 adds an additional risk of breast carcinoma, but not excess weight under the age of 50 (Kumar et al, 1995; Ziegler et al, 1996; Honda et al, 1999).

Many studies have assessed the effect of diet on breast cancer risk.

#### Fats

Diet

An early, widely accepted, hypothesis was that a high fat diet was directly related to an increased breast carcinoma risk (Armstrong and Doll, 1975; Wynder et al, 1986). However recent cohort and case control studies have failed to show a direct relationship between dietary fat and breast cancer (Jones et al, 1987; Phillips et al, 1980; Kinlen, 1982; Cade et al, 1998; Holmes et al, 1999) although the theory is still accepted by some (Walker et al, 1995; La Vecchia et al, 1998).

Dietary fat intake in the form of olive oil has been reported to reduce the risk of breast cancer in populations in Spain and Greece (Trichopoulou et al, 1995; Rose, 1997); this effect was found to apply equally to pre and post menopausal breast cancer. Olive oil forms a major component of dietary fat in the Mediterranean and is proposed to be a factor contributing to the low incidence of breast cancer in this region (Hunter and Willett, 1996). Fish oil has also been found to have a protective effect (Caygill et al, 1996; deDeckere, 1999).

# Isoflavones and lignans

Isoflavones, present in tofu and other non fermented soya bean products may lower the risk of breast cancer (Maskarinec et al, 1998). Wu et al (1996b) discusses the correlation between the high rate of tofu consumption by Asian populations and their lower risk for breast, colon and prostate cancer, and suggests that the reduced tofu consumption found in migrant Asian populations to the USA may partially explain the increased breast cancer risk of this population when compared with that in Asia. The apparent protective effect of high levels of tofu consumption applied equally to pre and post menopausal breast cancer (Wu et al, 1996b; Ingram et al, 1997). Synergistic effects have been reported with curcumin in oestrogen receptor positive cell lines reducing cell proliferation (Verma et al, 1997).

Lignans are found in a wide range of foods including legumes, and whole grain and have oestrogenic and anti oestrogenic effect (Verma et al, 1997; Bingham et al, 1998), and may lower the risk of breast cancer (Ingram et al, 1997).

# Curcumoids

Curcumin the major biologically active component found in turmeric (*Curcuma longa*), has a cytostatic effect inhibiting cell division at the G2/M check point (Simon et al, 1998). The compound has also been shown to compete with hydrocarbons as a ligand

#### 44

and substrate for the aryl hydrocarbon receptor pathway, and so actively protects against a wide range of pollutants including pesticides (Ciolino et al, 1998). *Alcohol* 

A positive relationship between alcohol intake and increased risk of breast cancer has also been reported with even moderate alcohol intake increasing endogenous oestrogen levels (Hunter and Willett, 1996; Viel et al, 1997).

## Well cooked meat

Well cooked, or over cooked, meats resulting from very high cooking temperatures are a potential source of heterocyclic amines which are potent mutagens. Regular consumption of such meats have been associated with an increased risk of breast cancer (Djuric et al, 1998; Zheng et al, 1998).

With age the individuals cumulative exposure to oestrogen and carcinogenic agents increases. Relationships between age and breast cancer are discussed further in sections 2.1.2, 2.1.3 and 3.1.2.

# 2.1.2 MODELS OF BREAST CANCER INCIDENCE

Mathematical models in the study of breast cancer can be used to demonstrate the consistancy of available data with a particular biological hypothesis, or to model the expected out come assuming a given biological hypothesis. For a model to be valid the biological basis for the hypothesis should be as sound as possible, and even then this will be only one alternative, as several biological models could be consistent with the observed data.

The incidence of most epithelial cancers increases steadily with age, cancer being most common in the old, and fits well to the mathematical model

## incidence = $C(age)^{\alpha}$

where C is a constant representing exposure or risk and alpha represents the number of stages in the carcinogenic process (Armitage and Doll, 1961; Doll, 1971). However breast carcinoma does not fit into this simple model since age incidence curves for breast carcinoma do not rise proportionally with age. The rate of increase prior to 50 years steadily increases with age and continues to increase after the age of 50, but at a slower rate, this inflection at the age of menopause is known as Clemmesen's hook (Clemmesen, 1948). Models have been proposed to explain Clemmesen's hook:

De Waard proposed (1969) the possible existence of more than one type of breast cancer, and that the incidence curves for breast cancer seen in different countries comprised the sum of the premenopausal "ovarian" type and the postmenopausal

45

"extraovarian" type. De Waard, (1979), analysed ASIR data from the first three volumes of Cancer Incidence in Five Continents and found that data from several countries, notably Japan and Taiwan, produced ASIR curves different from those seen in data from Western countries; DeWaard referred to these curves as "oriental" type. The "oriental" type curve tended to go up until about the age of 50 and then slowly decreased unlike the classical curve seen in Northern Europe and North America which continues to increase after the Clemmesens hook inflexion. Southern Europeans, Eastern Europeans, Latin Americans and Africans were described as having an intermediate type of curve. De Waard (1979) correlated the "Western" curve to the postmenopausal extra ovarian type and the "Oriental" curve to the premenopausal ovarian oestrogen type. The degree that a population is susceptible to premenopausal type breast cancer influences the position of Clemmesens Hook. The international differences in the incidence of postmenopausal type breast cancer he related to Western nutrition and in particular total fat intake.

Hakama (1969) produced a mathematical model of de Waards hypothesis, and showed that the two disease model fitted the ASIR data from four Nordic countries (Hakama, 1970). Hakama's model assumes two types of breast cancer, pre and post menopausal, both of which are represented by a polynomic quadratic equation of the form:

 $Y = \beta_0 + \beta_1 X + \beta_2 X^2.$ 

Where Y is equal to the log of the incidence, X is age and  $\beta$ 's are population specific constants. The position of Clemmesens hook is dependant on the proportion of pre and post menopausal breast cancer in the population. The model was criticised by Farewell (1979) because it requires 5-6 hypothetical stages in the process of breast carcer of white females in the United States, however supported the two disease hypothesis, and estimated that premenopausal breast cancer required seven events for carcinogenesis to occur and post menopausal breast cancer four events. The, then recent, work on colon cancer (section 1.3.4) made a multi stage model of breast neoplasia much more acceptable. Manton and Stallard (1980, 1992) suggested that premenopausal breast cancer is a more aggressive disease and that genetic factors influencing susceptibility to cancer were important in its aetiology, whereas post menopausal breast cancer was influenced more by epigenetic factors such as diet (Manton and Stallard, 1980). De Lisi (1977) derived a four parameter single disease model (Fig2.1). The model assumes that the menopause affects the rate of transition of hyperplastic to malignant

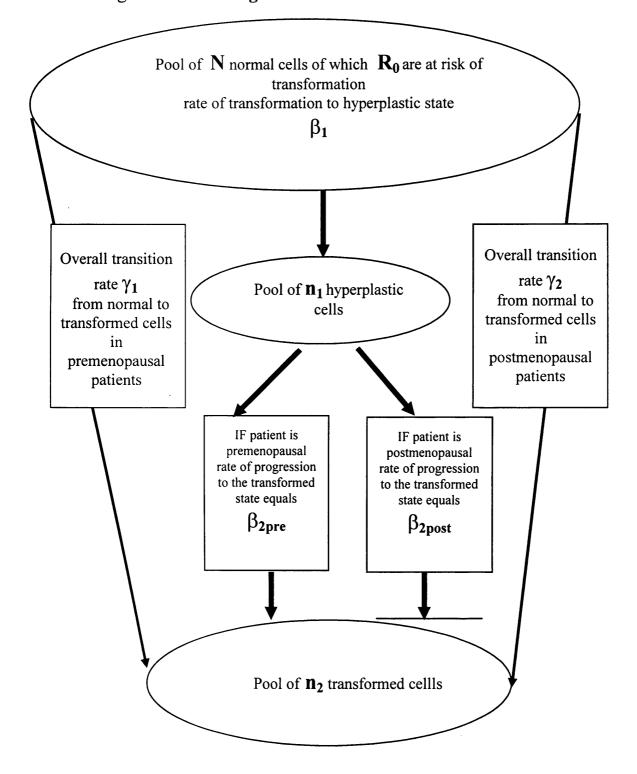

Fig 2.1 De Lisi single disease model for breast cancer

 $n_2$ , is the number of normal cells becoming fully transformed,  $\gamma_1$  the rate at which this occurs before menopause,  $\gamma_2$  the rate after menopause, and a factor  $R_0$  representing the apparent at risk fraction of the population cells. In the model, N is the pool of normal cells n1 become hyperplastic at a rate of  $\beta_1$  of which  $n_2$  cells then progress to the fully transformed state at a rate of  $\beta_2$ .  $\beta_1$  is a constant rate, however  $\beta_2$  varies being  $\beta_{2pre}$  premenopausally and  $\beta_{2post}$  postmenopausally, with  $\beta_{2post}$  being less than  $\beta_{2pre}$ .

cells. This results in a model in which although the rates of pre and post menopausal cancer can vary from population to population, they always pivot around a Clemmesen's hook fixed at the time of the menopause.

Moolgavkar et al (1980) formulated a two-stage single disease model of breast cancer (Fig 2.2). The model does not consider pre and postmenopausal breast cancer to be separate entities and attributes the apparent variation in the age specific incidence curves seen in different ethnic groups to cohort effect (Moolgavkar, 1979; Moolgavkar et al, 1980).

The source of data for the international comparisons from which these models were derived is the national and regional tumour registries of those countries and is therefore dependent on the reliability and accuracy of that registry data.

#### 2.1.3 TUMOUR REGISTRY DATA

Tumour registry data depends on several sources of information, any of which can introduce error and affect the reliability of the data.

#### **Potential sources of error**

#### Population estimation

Incomplete or inaccurate census data can result in artifactual ASIR results. Even relatively recent census data from some regions in the USA have been found to have not been fully reliable, especially data concerning the population over 65 years of age and non whites (Doll and Peto, 1981).

#### Sources of registry data

Death certificate data is generally a less reliable source of data and particularly prone to under diagnosis in the older age groups, where death may be easily attributed to other causes or a cancer may be so widely disseminated that its primary site is no longer obvious. The reported incidence of new cases is preferable, especially if supported by histopathological data.

#### Errors in registration

Apart from errors in entering data and inadequate quality control procedure, other sources of error may be caused by patients registering at more than one hospital. The danger is that this may result in aberrations that may be mistaken for trends, which may swamp out any real underlying trends. All of these components vary from registry to registry and directly affect the quality of data produced.

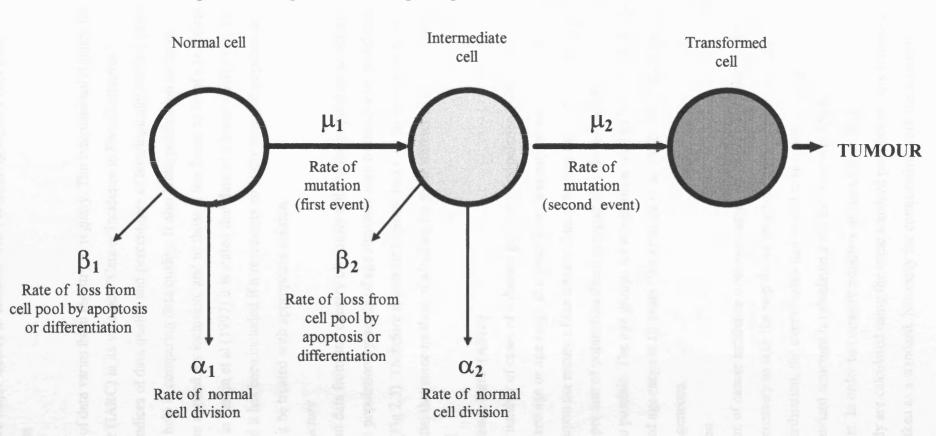

Fig 2.2 Moolgavkar two stage single disease model for breast cancer

N is the pool of normal cells capable of cell division and thus susceptible to mutation,  $\beta$  the rate at which cells become no longer capable of division (either through apoptosis or differentiation),  $\alpha$  the rate of cell division, and  $\mu$  the transition rate from one stage to another in the model.

#### Comparison of data between registries

There are two major factors to consider when comparing registry data from different populations

#### The quality of data

The quality of data varies from registry to registry. The International Agency for Research on Cancer (IARC) in its volumes "Cancer Incidence in Five Continents" includes a table of indices of data quality and percentages of histologically verified cases for each registry to help in comparing data quality. It also limits publication to those registries which have applied for inclusion, and to those it has found to be of a sufficient standard. However in Parkin et al (1997) it is stated that data of a lower quality may be considered valid and it has been included if it represents an under reported population, but it suggests that it be treated with appropriate caution.

#### The population structure

Crude patient data from any country obviously reflects the population structure of that country. The population pyramids of age structure vary tremendously in different areas of the world (Fig 2.3). Therefore if tumour registry data is to be compared between registries it is essential that some method of allowing for these difference in population structure be utilised.

#### Age Specific Incidence Rate (ASIR)

ASIR is the number of cases of a disease per unit of population (100,000 individuals) for a given age or age range at a given time, and may or may not be sex specific dependant upon the nature of the disease. Since the incidence rate for each age group is calculated per unit of population direct comparison between ASIR from different registries is possible. The age groups for comparison need to be quite small; the largest recommended age range is 10 years (Waterhouse et al, 1982) since larger ranges might be too heterogeneous.

#### Age standardisation

If comparison of cancer incidence over age ranges spanning more than 10 years is required then it is necessary to take the population structure of the country or region into account. Age standardisation, the overall rates that would have occurred if the population had a standard structure is calculated from the observed ASIR in the population of interest. In order to compare populations the overall rates for all the countries under study are calculated using the same standard population. Any reference population can be taken as a standard. Normally for comparative work the standard population is either:

# Fig 2.3 Standard Populations

## Standardised breakdown of a total population of 100,000 into different age groups. Each standard population having a different age distribution $\phi = 1000$ individuals

| Age     | African               | World                 | European        |
|---------|-----------------------|-----------------------|-----------------|
| over 75 | •                     | + +                   | * * * *         |
| 70-74   | •                     | <b>+ +</b>            | * * *           |
| 65-69   | •                     | * * *                 | * * * *         |

Developing countries have bottom heavy pyramids in with a large young population and relatively few in the older age group European populations have proportionally more older but less younger population.

(Adapted from Parkin et al 1997)

#### 1.African 0 - 85 years of age;

a low proportion of persons in the older age groups

2.European 0-85 years of age;

a low proportion of persons in the younger age groups

3.World 0-85 years of age;

a population structure intermediate between the African and the European.

4. World truncated 35 - 65 years of age;

a truncated form of the standard world population.

Unless both populations that are being compared come from Africa, or both come from Europe, it is usual (Parkin et al, 1997) to use the World standard or the World truncated standard for comparison.

# 2.1.4 STANDARDISED INCIDENCE AND AGE SPECIFIC INCIDENCE RATES OF BREAST CANCER IN DIFFERENT ETHNIC GROUPS

Geographic differences in incidence of breast cancer exist (Parkin et al, 1992; Kelsey and Horn-Ross, 1993; Gilliland, 1997) and these differences appear to be both qualitative and quantitative. In areas of low incidence, such as Japan, the disease has a major premenopausal element and slowly decreases after the age of 50. In areas of high incidence such as the USA and UK age specific incidence data (ASIR) (Parkin et al, 1994) shows the disease to be more common in postmenopausal women with an age specific increase premenopausally, followed by a slower rate of increase after menopause to form the classic Clemmesen's hook effect.

De Waard (1979) described Japan and Taiwan as having the lowest incidence and predominantly premenopausal type breast cancer and Northern Europe and North America having the highest incidence and post menopausal type breast cancer. The countries of Southern and Eastern Europe, South America, and Africa were intermediate between these two extremes.

It has been proposed that the ethnic differences might be related to differences in inherited tumour susceptibility (Gilliland, 1997). However the 'Oriental' and 'Western' patterns of breast cancer and ethnic variation in age specific incidence have been discounted by some researchers as being due to differential risks in various cohorts (Moolgavkar et al, 1979; Stevens et al, 1982), which once allowed for statistically result in a more standardised curve, irrespective of the ethnic origin of the population (Moolgavkar et al, 1980). The variation in age of onset and differences in the patterns of incidence between various countries with high and low breast cancer incidence are examined in detail later in this chapter.

#### Temporal changes of standardised incidence

Incidence rates of breast cancer are increasing in all countries (Wang et al, 1998). It has been reported that the increased incidence of breast cancer is particularly notable in the developing countries (Kelsey and Horn-Ross, 1993) and in those countries which have previously had a lower incidence of breast cancer (Patavino et al, 1995) and is frequently attributed to environmental risk factors associated with the adoption of a Western life style. Stephens (1997) however reports that breast cancer in the West has increased more than in Asian countries and attributes the difference to one of diet. Some of the increase seen during the last 20 years is probably due to greater public awareness and improved detection methods. This is particularly true in developed countries where asymptomatic breast tumours are now being detected through mammographic screening programmes and may lead to an increase in incidence of breast cancer in the screened population (primarily the 50 - 65 year olds); such an apparent increase was reported in Finland after nation wide screening was introduced (Gastrin, 1980). Cohort effects, when more recent cohorts show a greater incidence of breast cancer which could be due to the reduction of family size, older age at first birth, reduced period of breast feeding, dietary changes etc., have also been used to explain temporal changes, especially the increase in pre menopausal breast cancer (Wang et al, 1998).

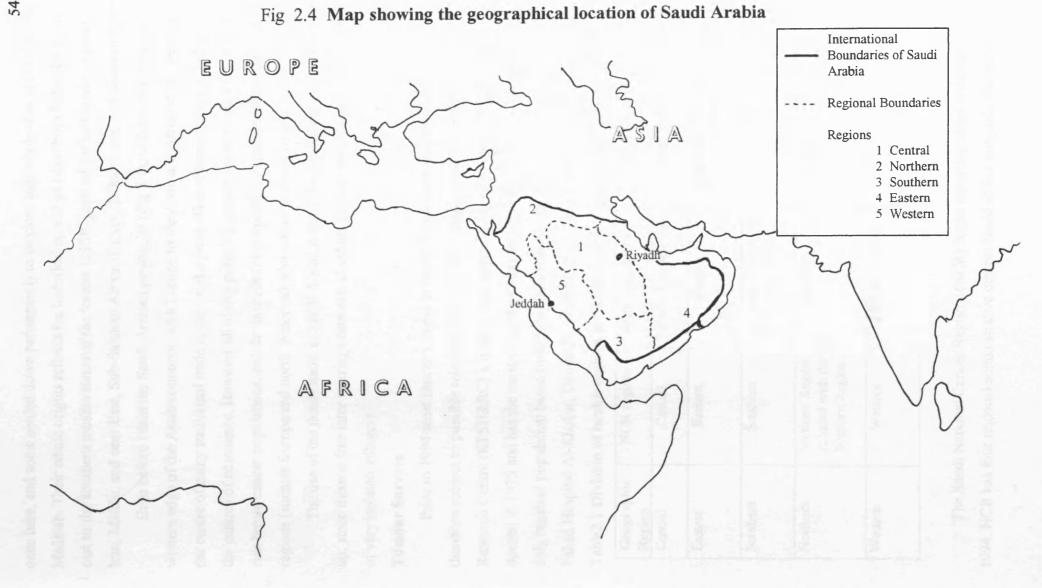

Manton and Stallard (1980) however argue that since reproductive factors such as early menopause and early first pregnancy confer a degree of protection against breast cancer into old age, removal or reduction of these factors is unlikely to cause an increase in premenopausal breast cancer. Similarly obesity, caused by dietary changes, has most effect in the post menopausal age group (Kumar et al, 1995).

#### 2.1.5 BREAST CANCER IN SAUDI ARABIA

Saudi Arabia is a large country, approximately 2.15 million square kilometres, (Fig 2.4) comprising of five geographical regions, central, southern, northern, eastern, and western regions. Jeddah, the city from which the detailed study population is drawn is situated in the western region on the Red Sea coast approximately 80kms from Makkah and 400 km from Madinah.

#### The Ethnic groups in Saudi Arabia

The population in the Western Region of Saudi Arabia comprises tribal Arabs, and other ethnic groups. In the past it used to take many months to reach Saudi Arabia by sea and land and it was not uncommon for pilgrims (Hadji) to stay for a period

once here, and some settled down permanently to be close to the holy sites of Makkah and Madinah. Their ethnic origins reflects the historical spread of Islam from Indonesia in the east to the southern muslim states of the former USSR, parts of the Indian sub continent, Iran, Middle, and near East, Sub-Saharan Africa, Turkey, Baltic states, and southern Spain.

Even before Islam the Saudi Arabian peninsular (Fig 2.4), situated as it is on the western edge of the Asian continent, with Europe to the north and Africa to the west, was the centre of many traditional trade routes, and a proportion of these traders would settle in the centres of commerce. However all of this potential genetic input comes from other low risk breast cancer populations, and far exceeds the proportion of persons from high risk regions (such as Europe and north America) who settled in Saudi Arabia.

The use of the family name in Saudi Arabia is not a reliable indicator of ethnic make up, since there is free inter marriage between all ethnic groups (with the possible exception of very isolated villages).

#### **Tumour Surveys**

Prior to 1994 most cancer surveys in Saudi Arabia were hospital based, and therefore subject to possible selection bias. The King Faisal Specialist Hospital and Research Centre (KFSH&RC) a tertiary care referral hospital located in Riyadh, was opened in 1975 and has the most complete source of hospital based cancer statistics. The only regional population based tumour registry was for the Eastern Region at King Fahad Hospital Al-Khobar, Dammam, established in 1985 (Tamimi et al, 1995).

| Geographic<br>Region | NCR regions  | Reporting Regions            | Health Regions                      |

|  | Table2.1 | <b>Division</b> ( | )f health | regions in | Saudi | Arabia |
|--|----------|-------------------|-----------|------------|-------|--------|
|--|----------|-------------------|-----------|------------|-------|--------|

The Saudi National Cancer Registry (NCR) began reporting cases in January 1994. NCR has four regional administrative centres based at five hospitals, the regions basically the geographical regions of the country (Fig 2.4). These are divided into 11 reporting regions (Fig 2.5) used in the NCR detailed reports, which can be further divided into 19 health regions (table 2.1). Earlier, pre-NCR reports used either geographic areas or health regions for their reports.

National and regional reports show breast cancer to be one of the top ranking female neoplasm in all of the regions (Table 2.2). Breast cancer is quoted in some studies as a percentage of adult malignancy, with no differentiation between male and female cases, and the age range of patients was not always included.

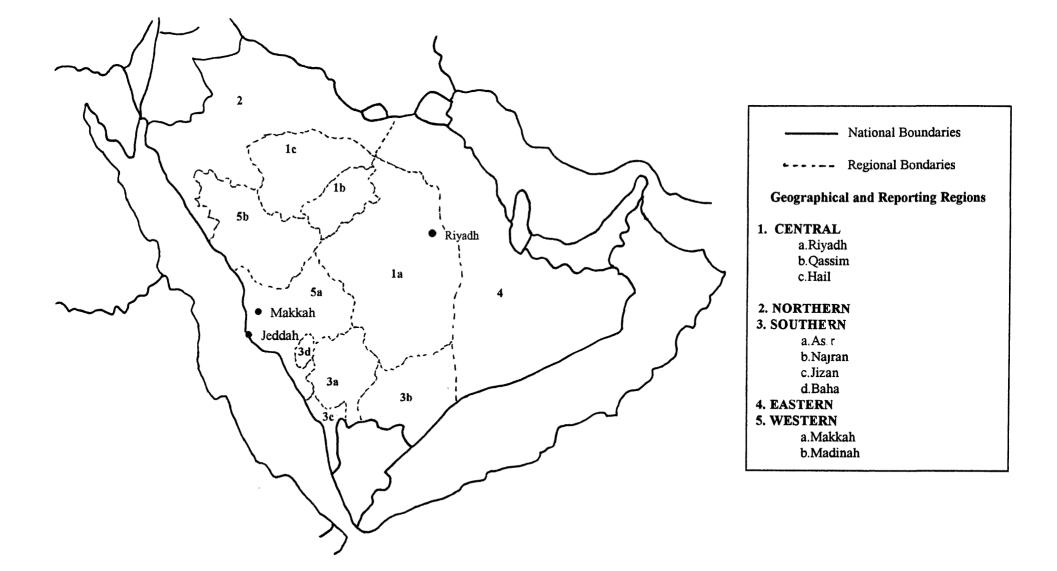

The situation in the Southern Region appears to be different than the other regions, with breast cancer being ranked third or fourth. The local habit, which is equally common among males and females, of chewing shamma (a mixture of tobacco, slaked lime, spices and oils), has been linked to the high level of oral cancer (Khan et al, 1991). Possible explanations as to the high incidence of skin cancer in the Southern region are the high altitude, or that skin cancer is treated locally and so over represented (Willen and Pettersson, 1989). It is probable, therefore, that the differences are due to an increased incidence of oral and skin cancers rather than a reduced incidence of breast cancer.

Saudi Arabia has a crude incidence rate of cancer of 38.1/100,000 (world age standardised rates ASR 80.9) (NCR 1996) compared with 401.8/100,000 (ASR 201.0) in the UK (Parkin et al, 1992). The crude incidence of breast cancer in Saudi Arabia of 6.5/100,000 (NCR 1996) and 88.3/100,000 in the UK (Parkin et al, 1992). Breast cancer in Saudi Arabia still represents about 18% of all female malignancies (NCR 1996).

It has been suggested that reluctance to seek medical attention and environmental risk factors are responsible for the observed pattern of breast cancer in Saudi Arabia (Amer, 1982; Ajarim, 1992). A report by Al Idrissi et al (1992) states that post menopausal patients delay on average 12+/-2.3 months prior to seeking medical attention, whereas in pre menopausal patients the delay is only 4+/-0.57 months, and yet pre menopausal patients were presenting with more advanced disease than the postmenopausal patients. This suggests that any delay in treatment does not explain the observed differences between pre menopausal and post menopausal breast cancer in Saudi Arabia.

With the exception of obesity the female population of Saudi Arabia and the Arabian Peninsula exhibit no obvious high risk environmental risk factors. Obesity in the Saudi female population appears to be mainly pre and peri menopausal women (El Hazmi and Warsy, 1997) and studies have shown that it is excess weight over the age of 60 that results in an additional risk of breast cancer (Kumar et al, 1995).

Table 2.2 Outline of breast cancer in Saudi Arabia, by region

a:Ezzat et al 1996, b:Koriech and Al-Kuhaymi 1984, c: Al-Salah 1994, d:Willen and Petterson 1989, e:Tandon et al 1995, f:Rabadi 1987, g:Amr et al 1995, h:Al-Saigh et al 1995, i: Mokhtar and Bedeiwy 1992. This would not be expected to increase the incidence of pre menopausal breast cancer. Increased body size in young women may even decrease the risk of premenopausal breast cancer (Peacock et al, 1999), although others (Coates et al, 1999) have found the situation more complex and this advantage confined to the less aggressive tumours only. Several of the factors exhibited by the Saudi population are thought to protect against breast cancer; therefore environmental risk factors may help explain the low overall incidence of breast cancer in Saudi Arabia and the region, but do not explain the apparent excess of young breast cancer patients.

| Environmental<br>risk factors | Assessment in Saudi/Arab population   |
|-------------------------------|---|
| Reproductive                  | Menarche 13.07 +/- 0.91 years <sup>a</sup> , mean age at first full pregnancy 21 years <sup>b</sup> , menopause 49.3 +/- 4.6years <sup>c</sup>  |
| OC use                        | Of females who use contraception, 43% use the IUD and 6.9% OC, only 25% using contraceptives before the birth of their first baby <sup>d</sup>  |
| Diet                          | 3265 kcal/caput/day of which 10.9 % come from oils and fats <sup>e</sup><br>Given the strict prohibition laws in Saudi about alcohol<br>consumption it is reasonable to assume that the average<br>consumption per head of female population in Saudi is<br>infinitely smaller than that in the West. |
| Obesity                       | Saudi females are more obese than their European counterparts <sup>f</sup>  |
| Breast feeding                | In urban areas the majority, 72%, of babies are breast fed for at least 3 months, 11% are fed for at least a year. In rural areas the majority of babies are breast fed for over a year. <sup>g</sup>   |

a-(Attallah et al, 1990) b: (pers comm. Dr H.Qardi) c: (Qattan and Omu, 1996)

d: (Bakr and Suliman, 1990) e: (Ministry of Agriculture and Water, KSA 1983)

f: (Al Rehaimi and Bjorntorp, 1992) g: (Al-Shehri et al, 1995)

This pattern of high relative incidence of breast cancer against a background of low overall levels of neoplasia and young age of occurrence is not unique to Saudi Arabia and has been noted in other low risk populations.

#### 2.1.6 BREAST CANCER IN OTHER LOW RISK POPULATIONS

#### Middle East

Studies from Egypt (Richards et al, 1992; Kahan et al, 1997; Soliman et al, 1999), Kuwait (Motawy et al, 1994), Lebenon (Adib et al, 1998; El Saghir et al, 1998) and Libiya (Akhtar et al, 1993), all report breast cancer as being the most common

female malignancy, and presenting at a young age with a high proportion of premenopausal patients.

The Israeli tumour registry divides its reports into incidence in Jews and non Jews; the non Jews being primarily Christian and Moslem Palestinians. Data is also available on the ASIR of cancer among Jewish Israelis belonging to different ethnic groups. Incidence rates vary Palestinians having the lowest and Jews born in America or Europe the highest (Steinitz et al, 1989). The incidence for European/American born Jews is four fold that found in the Palestinian population. Peak incidence occurs at 70+ for the Israeli Jewish patients and at 45 years of age in the Palestinian patients (Parkin et al, 1992). In a study of the Jewish migrant populations (Steinitz et al, 1989) the incidence of breast cancer changed only slightly with time, not showing the relatively rapid changes as described by Haenszel and Kurihara (1968) for Japanese migrants to the USA. However Steintz et al (1989) studying female breast cancer cases aged 0 -75+, found Asian immigrants to Israel had the lowest overall incidence rate, but in a study of 3<sup>rd</sup> generation Israelis 0-29 years (Iscovich and Parkin, 1998) incidence was found to be notably higher among females of Asian descent.

#### Africa

Studies from Sub-Saharan Africa report a low overall incidence of neoplasia but a high proportion of premenopausal breast cancer (Bjerregaard and Kung'u, 1992; Hassan et al, 1992; Amir et al, 1996; Adebamowo and Adekunle, 1999).

#### South East Asia

The overall incidence of breast cancer is lower in Japan but breast cancer still represents one of the most common neoplasms affecting females. In a study of ASIR of breast cancer in the Japanese female population and the British female population Kodama et al (1992) described a rising incidence with age for the Japanese population until a break point at 47.5 years when there was a gradual decline, whereas the British population exhibited the classical western pattern of breast cancer described earlier. A study by Hirose et al (1995) described breast cancer in Japan to be primarily a premenopausal disease. There is some evidence to suggest that differences in the classical epigenetic risk factors may not be sufficient to explain differences in the incidence and pattern of breast cancer in Britain and Japan (Chaudary et al, 1991; Tung et al, 1999). Merchant et al (1999) studying British and Japanese breast cancer patients found Japanese patients to be significantly younger.

Breast cancer accounts for about 20% of female malignancy in India (Goel et al, 1995) the majority of patients being premenopausal (Hussain et al, 1994).

#### **Migrants from low risk populations**

Migrants from the Near and Middle East to Australia and France have been reported as having a low overall incidence of neoplasia and breast cancer (Khlat et al, 1993; Khlat, 1995). Asian migrants from the Indian sub-continent to New South Wales, Australia were found to have a lower overall incidence of cancer, with an incidence of breast cancer intermediate between that found in the sub-continent and Australia. (Grulich et al, 1995).

#### **USA minority populations**

Incidence rates 40 -54 years in White American women (AmW) are higher than those seen in Black American women (AmB), however in women under the age of 40 there is an excess incidence in the AmB population which cannot apparently be attributed to reproductive factors (Brinton et al, 1997). There is also a marked transition from higher to lower incidence rates at the age of 45, not seen in AmW, which cannot be accounted for by other known risk factors (Hankey et al, 1994; Trock, 1996). Generally AmB patients present at a younger age (Aziz et al, 1999) than AmW and the same is true for Hispanic Americans (AmH) and Asian Americans (AmA) (Boyer-Chammard et al, 1999). AmB patients have been reported to be at a higher risk for premenopausal breast cancer than their AmW counterparts, and this increased risk persists even after all known confounding factors have been taken into account (Weiss et al, 1996). Ijaduola and Smith (1998) comparing AmW, AmB and West Africans (WAf) found both AmB and WAf to have a peak incidence of breast cancer below the age of 50 years, whereas that in AmW is postmenopausal.

The lower standardised incidence of breast cancer in the AmH population (Davis et al, 1995) suggests that AmH might still retain some of the lower risk profile of their home despite being exposed to the environmental risk factors prevalent in the USA. However many studies have shown that upon emigration to the USA the risk of breast cancer in Asian women (Japanese, Filipino, Chinese) approaches that of AmW after a few generations (Haenszel and Kurihara, 1968; Buell,1973; Fraumeni and Mason, 1974; Thomas, 1979), emphasising the impact of environmental risk factors, probably associated with western life style, on breast cancer incidence.

#### 2.1.7 BREAST CANCER IN THE BRITISH ASIAN COMMUNITY

Several studies have found the overall incidence of cancer lower in the British Asian than in the non Asian community (Donaldson and Taylor, 1983; Winter et al, 1999) and that breast cancer incidence is lower, but the most common form of cancer affecting females (Potter et al, 1983; Donaldson and Clayton, 1984; Barker and Baker, 1990; Winter et al, 1999). Potter et al (1983) in a hospital based study in Birmingham concluded that the differences in breast cancer incidence could not be explained by differences in reproductive factors alone and were similar to incidence rates in their countries of origin. Similar results were obtained by Winter et al (1999). Breast cancer incidence in the UK South Asian population was found to be approximately half way between that of the UK and India. ASIR data was examined for cancer at all sites for the same populations, Winter et al (1999) concluded that there are underlying differences in ethnic incidence even after age structure has been taken into account. A high incidence of young breast cancer in the S.Asian UK population, below 29 years, was noted but this was attributed to a probable cohort effect requiring longer follow up.

The study of cancer epidemiology in different ethnic groups will be made easier once the mandatory requirement that ethnic data be included as part of patient admission documentation (Bahl, 1996) becomes effective and such data is routinely included in tumour registries.

### **2.2 AIMS:**

The aims of this chapter are to

Analyse differences in overall standardised incidence and age specific incidence rates (ASIR) in populations of high and low incidence of breast cancer in general, and in the study populations in particular. This analysis will attempt to ascertain whether the larger proportion of young cases found in the Western Region can be attributed to a different presentation of breast carcinoma or whether it is an artefact of the population structure. The relative impact breast cancer has at different ages and in different ethnic groups, when compared with the incidence of cancer at all sites, will also be examined for the study populations.

#### **2.3 MATERIALS**

Data was collected from a variety of sources for comparison of the patterns of incidence of female breast cancer in the Western Region of Saudi Arabia and Trent UK with respect to breast cancer incidence in other low and high incidence countries.

#### 2.3.1 INTERNATIONAL DATA

The Israeli Asian/African and Israeli European Jewish data were from Steinitz et al (1989), and other countries were from Parkin et al (1992), Parkin et al (1997) and Waterhouse et al (1976).

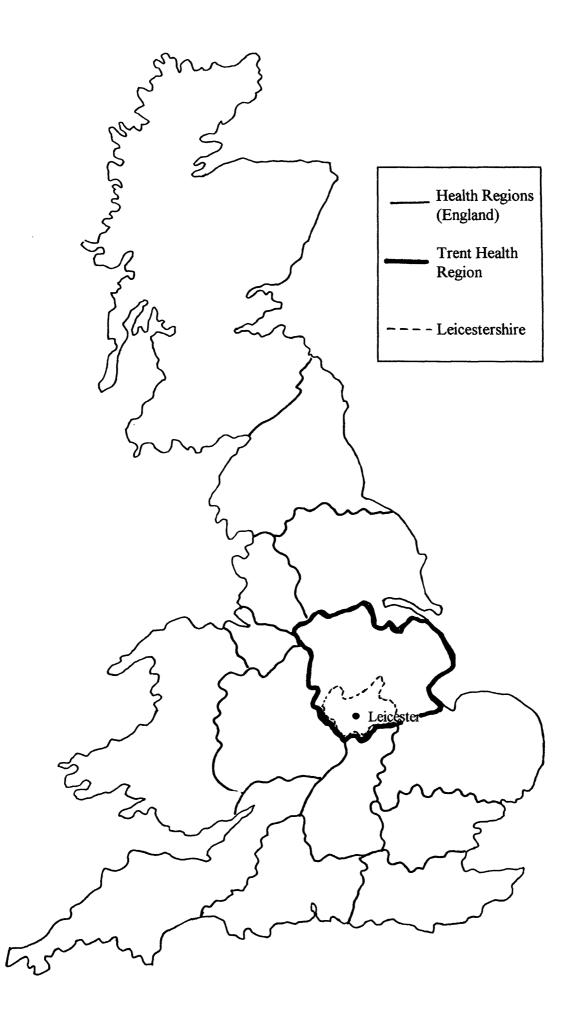

# 2.3.2 BREAST CANCER DATA IN THE WESTERN REGION OF SAUDI ARABIA, TRENT AND LEICESTERSHIRE

#### i.Western Region of Saudi Arabia

Data was obtained for breast cancer and for all cases of cancer occurring in the Saudi adult female population of the Western Region of Saudi Arabia (Figs 2.4, 2.5) from the Western Region NCR Office, for a three year period, 1994-1996. National incidence rate for Saudi Arabia and ASIR for the Western Region of Saudi Arabia was obtained from the NCR report for 1994-1996. The NCR report gives the incidence of breast cancer in Makkah district, and this was used to calculate the population of the Makkah district. The sex specific age structure was estimated from the census data of 1977 for the Makkah district (see discussion).

#### ii Trent Health Region In The United Kingdom

Data for the UK and Wales and regional UK data for the Trent Health Region was obtained from Cancer Incidence in Five Continents vol. VI. The data for female breast cancer patients from Leicestershire (population approx.900,000) which forms part of the Trent Region (Fig 2.6) was compiled from the computerised records of the Leicestershire Pathology Service, covering 1994 - 1996. Malignant cases were extracted and classed either as Asians or non Asians, according to name, and their age at presentation age calculated from their date of birth. The total number of malignant cases (Asians + non Asians) was checked on a hospital by hospital basis against the total numbers of malignant cases, previously compiled by Dr Walker, to ensure that no cases had been missed. Data was obtained from the 1991 census data for Leicestershire which gives both total population and ethnic breakdown by age. For the purpose of this study persons of Indian, Pakistani, and Bangladeshi, were treated as a single group as it would be very difficult to distinguish between then by name.

## **2.4 METHODS**

# 2.4.1 DETERMINATION OF THE COMPARATIVE STATISTICAL MEASUREMENTS ASIR, SIR, reISIR, AND AVERAGE AGE OF ONSET

International data for ASIR was extracted from vols III, VII 'Cancer Incidence in Five Continents' (Waterhouse et al, 1976; Parkin et al, 1997), and from Steinitz et al (1989). SIR was also available from these sources with only minor modifications. ASIR data for the Trent region was obtained from 'Cancer Incidence in Five Continents vol VI' (Parkin et al, 1992).

ASIR and SIR for the Western Region of Saudi Arabia, and ASIR for Leicestershire Europeans and Asians was calculated from patient record data of the NCR and Leicestershire Pathology Service. Rel SIR, and average age of onset was calculated in all cases. Data was entered into Excell 7.

#### ASIR

To calculate ASIR it is necessary to know, or be able to derive, the total population (affected and non affected) of the study region, and the number and ages of affected persons in that region.

#### Calculation of ASIR for Saudi woman in the Western Region of Saudi Arabia

The NCR is compiled on EPI INFO 6; this was transferred to Excell 7. Data was sorted according to site, sex and age; breast cases were selected and male cases deleted. This was performed for 1994, 1995, and 1996 and the resulting files merged. Manipulation of the raw data in the spread sheet was performed by creating suitable equations and macros in Excell 7.

Cases from Makkah district are identifiable in the NCR records by the hospital code, and all cases had details of nationality. It was therefore possible to find the number of new Saudi cases of breast cancer in the Makkah district reported for 1994. By utilising this figure and the crude incidence rate for breast cancer in Saudi females in the Makkah district quoted for 1994, the population of Makkah district could be calculated. The age structure for the female Saudi population of Makkah district was calculated from the 1977 population census (Central department of statistics, 1977) and was assumed to be representative for that of the whole of the Western Region. The total population for each age group in the Western Region was calculated. Knowing this and the total number of cases of female breast cancer occurring in each age group over a three year period (1994-1996), the ASIR for breast cancer was calculated.

Calculation of ASIR for the European and Asian Communities of Leicestershire

Trent region is not ethnically homogeneous and includes a sub set of British Asians. The Leicestershire data base has the advantage over the Trent data in that the Asian and European sub populations can be identified. The Leicester Asians (AL) in the database were identified as Asian by name; this method has been shown to be a satisfactory method of identifying Asian patients (Nicoll et al, 1986; Winter et al, 1999). The age specific data for the female populations of Indian, Pakistani, and Bangladeshi ethnic origin in Leicestershire was obtained from the 1991 census and used to produce age specific data for a combined Leicestershire Asian female population. This and the number of breast cancer cases occurring in this population during 1994 to 1997 was used to calculate the ASIR for the AL breast cancer population. The mean and standard deviation for grouped data was calculated for the AL population.

The ASIR for the Leicester European breast cancer population (EL) was also calculated. The population EL from the Leicestershire data base was compared statistically with that for the Trent region. Using the age specific data for the total female European population of Leicestershire and the known number of breast cancer cases occurring in this population during 1995 and 1996 the ASIR was calculated. The mean and standard deviation for grouped data was calculated for the Leicestershire European breast cancer population.

The ASIR data from the three study populations was compared using a modified Mantel-Haenszel test (section 2.4.4).

#### **Standardised Incidence**

The standardised incidence rate (SIR) is the rate expected if the observed age specific rates had occurred in a standard population. The standardised incidence was compiled from published data, or, when such data was unavailable calculated according to the method outlined in Parkin et al (1992).

The calculation comprises the following steps:

The ASIR for each age group is multiplied by the number in that age group in the standard population. This is repeated for each age group. The numbers are added and the sum divided by the standard population.

The standard error is then calculated. The varience for each age group is calculated by multiplying the expected number in the standard population by the total number of persons in the standard population at that age group. The product is then divided by the number of years over which the data was collected multiplied by the actual number of persons in that age group in the study population. This is repeated for all age groups and the results summed. The square root is taken of this figure and divided by the total number of persons in the standardised population to obtain the standard error of the standardised rate.

#### Standardised Incidence from International data, including the Trent Region

A spread-sheet was compiled from the data in the standardised incidence tables for breast cancer from Steinitz et al (1989), Parkin et al (1992), and Parkin et al (1997). In order to present the maximum data spread, the incidence of breast cancer in a country was calculated plus and minus the standard deviation when available. Where countries had results from more than one registry, the median value was calculated, and also values plus or minus the maximum standard deviation between the contributing registries. Excell 7 was used for data manipulation.

#### Standardised Incidence of breast cancer in the Western Region

The NCR report only provided the crude incidence rate for female breast cancer in the Western Region, therefore to allow comparison of the total incidence with other registries it was necessary to standardise the rate. The standardised incidence rate for female breast cancer in the Western Region of Saudi Arabia and the estimated standard error was calculated with the world population as the standard (Fig 2.4 section 2.1.3) using the methods described by Parkin et al (1997) utilising the Excell 7 software worksheet.

#### RelSIR

RelSIR is equal to the SIR of a given cancer divided by SIR for cancers at all sites. The value of relSIR gives a measure of the relative proportion of the tumour burden attributable to breast carcinoma in a given population. RelSIR was calculated for the international data, and at five yearly age intervals for the Trent and Western Region breast cancer populations.

#### Average age of onset

The mean age, and standard deviation of age was calculated for each group using the standard methods for grouped data (Daniel et al, 1987). Calculations were made for the Western Region, Leicester Asians, Leicester Europeans, Trent and International data.

#### 2.4.2 COMPARISON OF STANDARDISED INCIDENCE RATES

A series of countries was selected for whom age standardised incidence rates were available; all incidence rates were standardised to the world standard population. These included African, Asian, Western European, Eastern European, Mediterranean European and North American. The ASIR data for the Western Region of Saudi Arabia was prepared and the standardised incidence rate calculated.

67

# Calculation of median incidence and allocation of countries into high and low incidence groups

The median standardised female breast cancer incidence rate was calculated and the populations were grouped into low or high incidence categories, according to whether their incidence was above or below the median. The mean and variance was calculated for both categories, and Z-tests performed to compare the categories. Populations were then recorded by geographic or ethnic origin and a chi squared analysis performed to assess the probability of the distribution of the populations found in the two incidence categories to be occurring at random.

# Comparison of standardised incidence rates over a twenty year period, between 1976 and 1997, in low and high incidence countries

Populations with records published in both Cancer in Five Continents vol. III (Waterhouse et al, 1976) and Cancer in Five Continents Vol. VII (Parkin et al, 1997) were selected and their standardised incidence rates for female breast cancer tabulated for 1976 and 1997. The data from each volume is identified as 1976 data and 1997 data; this refers to the publication date rather than the date of data collection (which varies slightly from population to population) but the overall time difference is still approximately twenty years.

Utilising the median value, low and high incidence categories for 1997 and 1976 were allocated. Populations were then recorded by geographic or ethnic origin and studied to see whether the same regional distribution was present for the low and high incidence categories as was seen in the initial 1997 analysis. The difference between the rates for 1997 and 1976 between the populations was calculated, tabulated and a Z test utilised to compare any increase in low and high incidence countries.

#### SIR of cancer of all sites and relSIR of breast cancer between 1976 and 1997

Using the same data set, graphs were compiled of the total cancer incidence for all sites, and the relSIR, in order to get a measure of the relative proportion of the tumour burden attributable to breast carcinoma in the selected countries and how this varied over the twenty year period.

# 2.4.3 ASIR AND AGE OF ONSET OF BREAST CANCER IN SELECTED COUNTRIES WITH RESPECT TO THEIR LEVEL OF INCIDENCE ASIR

ASIR data for female breast cancer (NCR, 1996, Parkin et al, 1997), was entered into Excell 7 to form a spread sheet. When countries had entries from more than one registry, with no whole country registry, that with a level closest to the mid value of the incidence range was selected. A graph of log incidence against age was made for the selected countries, the incidence category to which they belonged being represented by different colours.

#### Age of Onset

The actual numbers of cases were either counted (for the Western Region of Saudi Arabia), or calculated from the group data in the spread sheets, and used for the calculations of the mean age, and standard deviation of age, using standard methods for grouped data (Daniel et al, 1987) for each group. The data was assessed using Z test analysis to find if there was a significant difference in the mean age of onset in high incidence and low incidence countries internationally.

# 2.4.4 BREAST CANCER INCIDENCE IN TRENT UK COMPARED WITH THE LEICESTERSHIRE EUROPEAN AND ASIAN SUBGROUPS AND THE WESTERN REGION. OF SAUDI ARABIA

The mean age of onset, the standard deviation and variance was calculated for Trent and the Western Region and a Z test performed to compare the mean age of onset of both populations. The mean age of onset, the standard deviation and variance were also calculated for the Leicester European and Leicester Asian sub groups, and Z tests performed.

#### ASIR, and relSIR

The rel SIR was calculated from the ASIR for breast and from ASIR for all sites for both the Western Region and Trent and examined graphically.

#### Mantel-Haenszel test on the ASIR data from the three study populations

The Mantel-Haenszel test method used is that detailed in Esteve et al (1994) for the comparison of incidence rates in two populations. The test takes as the null hypothesis that the age specific rates are equal, against the alternative hypothesis that the rates are proportional. A sample calculation, Western Region tested against Leicester Europeans for all age groups, is shown in fig2.7 using Excell 7. The test was used to compare the breast cancer populations of W.Region with EL, W.Region with AL, and AL with EL for age ranges: 20-69 years, 20-44 years, and 45-69 years The basic steps were: 1.The age specific frequencies for breast cancer in the two populations, k1 and k2,

were added to form combined age specific frequencies K.

W.Reg vs. EL

2. The number of person years in the general population for each age range was calculated for the two populations (i.e. the population at a given age multiplied by the number of years covered by the frequency data), m1 and m2, which were then added to form combined person years for each age group M.

3. The number of cases expected for population 2, if proportionality existed with population 1, were calculated (e2).

e2 = K x (m2/M)

4. The variance for cases in population 2 were also calculated

 $var(k2) = K x (m1 x m2) / M^{2}$ 

#### 5. The test statistic Z was calculated

$$Z = sum of observed - sum expected / square root of the variance$$

$$Z = \Sigma k2 - \Sigma e2 / \sqrt{var(k2)}$$

6. The test statistics were compared with the calculated critical value of Z

of 1.96 for a two tailed test at 95% confidence level.

# 2.4.5 AGE SPECIFIC RELATIVE RISK OF BREAST CANCER IN THE LEICESTERSHIRE ASIAN, LEICESTER EUROPEAN, AND WESTERN REGION BREAST CANCER POPULATIONS COMPARED TO THAT IN TRENT

For any cancer, dividing the ASIRs of two populations gives a measure of comparison of the relative risk of that cancer in the those populations (Breslow and Day, 1980). The ASIR of the three study groups was compared to that of Trent. ASIR are drawn on a log scale and the separation of the two lines gives a measure of relative risk (subtraction of the logs of two numbers is equivalent to dividing those numbers). If there exists, e.g. between two populations, a situation of constant relative risk irrespective of age, then the ASIR graph would be expected to show two parallel lines (Esteve et al, 1994), the difference between them being constant for all age groups.

In order to investigate any age specific differences in relative risk for breast cancer, the three populations were compared graphically with the Trent region. The ASIRs of the Western Region, the Leicestershire Europeans, and the Leicestershire Asian breast cancer populations were each divided by the ASIR for female breast cancer for the Trent region and the log of the quotient plotted against age.

# **2.5 RESULTS**

# 2.5.1 ASIR AND STANDARDISED INCIDENCE OF FEMALE BREAST CANCER IN THE WESTERN REGION OF SAUDI ARABIA ASIR

The ASIR data in table 2.4 shows a steady increase the 30-34 years old age group after which there is a slight decrease followed by a rise, until a peak is reached at the 55- 59 years old age group, and a subsequent decrease in ASIR. The data in Table 2.4 was used to plot Fig 2.13 section 2.5.5.

| Age<br>range | total    | male     | female   | male :<br>female<br>ratio | total number<br>female<br>breast<br>cancer cases<br>1994-96 | ASIR<br>of<br>female<br>breast<br>cancer |

 Table 2.4 Population structure and ASIR of female breast cancer in the Western

 Region of Saudi Arabia

#### Standardised incidence rate

Using the data in table 2.4 and the world standard population (Parkin et al, 1997), the standardised incidence rate for female breast cancer in the Western Region of Saudi Arabia was calculated as 14.89 per 100,000 females with a standard error of 0.01.

# 2.5.2 INTERNATIONAL INCIDENCE DATA FROM HIGH RISK AND LOW RISK POPULATIONS

| Low incidence countries      | upper limit | mean  | lower limit |
|------------------------------|-------------|-------|-------------|
| Korea                        | 8.6         | 7.1   | 5.6         |
| Algeria                      | 10.39       | 9.5   | 8.61        |
| Mali                         | 11.35       | 10.2  | 9.05        |
| Thailand                     | 15.9        | 11.5  | 7.1         |

#### Table 2.5 Incidence of female breast cancer in different countries

| High incidence countries | upper limit | mean | lower limit |
|--------------------------|-------------|------|-------------|
| Yugoslavia               | 44.37       | 43.6 | 42.83       |
| Czech Republic           | 45.45       | 45.1 | 44.75       |
| Slovenia                 | 47.03       | 46.2 | 45.37       |
| Spain                    | 53.9        | 46.9 | 39.9        |
| Philippines              | 48.58       | 47.7 | 46.82       |
| Germany (Eastern States) | 48.65       | 48.2 | 47.75       |
| Norway                   | 54.83       | 54.2 | 53.57       |
| Germany (Saarland)       | 62.73       | 61.5 | 60.27       |
| Eire                     | 66.31       | 64.2 | 62.09       |
| Austria                  | 66.68       | 64.9 | 63.12       |
| Finland                  | 65.56       | 65   | 64.44       |
| Italy                    | 74.5        | 65.2 | 55.9        |
| Switzerland              | 76.1        | 68.9 | 61.7        |
| UK                       | 77          | 72.7 | 68.4        |
| Sweden                   | 73.39       | 72.9 | 72.41       |
| Denmark                  | 73.94       | 73.3 | 72.66       |
| Netherlands              | 78.9        | 74.6 | 70.3        |
| France                   | 82.9        | 74.9 | 66.9        |
| Canada                   | 77.1        | 76.8 | 76.5        |
| Iceland                  | 82.45       | 79   | 75.55       |
| USA SEER Black           | 80.41       | 79.3 | 78.19       |
| Malta                    | 84.1        | 79.9 | 75.7        |
| European Jewish Israelis | 89.45       | 87.9 | 86.35       |
| USA SEER White           | 91.09       | 90.7 | 90.31       |

Table 2.5(cont.) Incidence of female breast cancer in different countries

The standardised incidence, based on the standard World population (Table 2.5) in different countries ranged from a mean of 7.1 in Korea to 90.7 in the SEER study of USA whites. The median incidence value was calculated as 43.6; countries with an incidence value less than this were classed as low incidence risk countries, and those with an incidence equal or greater than the median as high incidence risk countries.

To assess if the difference in incidence was statistically significant, the mean incidence and variance of breast carcinoma in low risk countries and high risk countries was calculated (Table 2.6).

|           | mean  | Standard deviation | Variance |
|-----------|-------|--------------------|----------|
| low risk  | 25.18 | 10.7               | 104.57   |
| high risk | 65.98 | 14.1               | 198.5    |

Table 2.6 Mean incidence and variance of breast carcinoma

in low risk and high risk regions

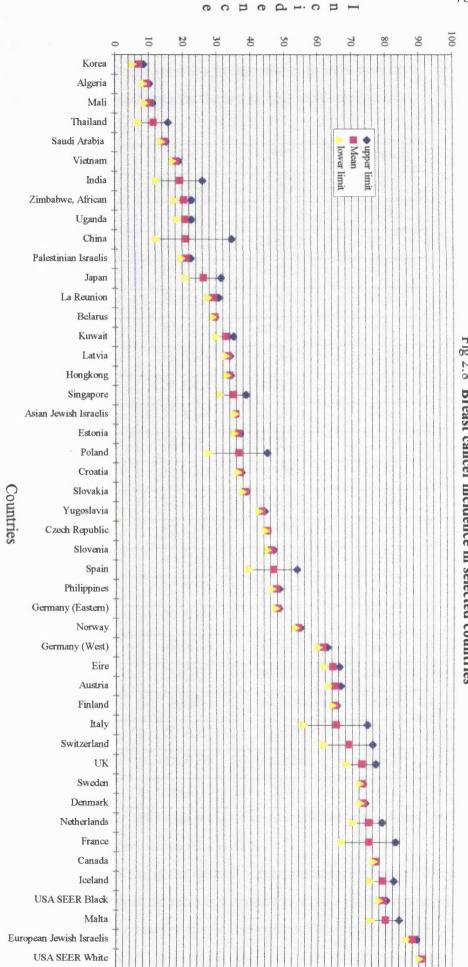

A Z-test for the comparison of two means resulted in a Z value of 11.39 which is greater than the critical Z value, at the 95% confidence level of 1.96, and there is therefore a significant difference between the incidence in the two groups.

Figure 2.8 is a graphical representation of the data in Table 2.5 and illustrates the level and ranges of incidence in the selected countries. The countries are ordered according to incidence rates and there is an apparent polarisation of Asian and African countries to the lower end of the incidence scale and European countries to the higher end. Populations were then recorded by geographic or ethnic origin and a chi squared analysis performed to assess the probability that the distribution of the populations into high and low incidence was occurring at random (Table 2.7).

| Table 2.7 Chi squared analysis | of the distribution of high and low incidence countries |
|--------------------------------|---|
|                                |   |

| Countries           | expected in<br>high<br>incidence<br>group | expected in<br>low incidence<br>group | observed in<br>high<br>incidence<br>group | observed in<br>low<br>incidence<br>group |
|---------------------|---|---------------------------------------|---|--|
| Mediterranean +     | 14  | 14                                    | 22  | 6  |
| European = 28       |   |                                       |   |  |
| African +Asian = 19 | 9.5                                       | 9.5                                   | 2   | 17                                       |

The chi squared value for the above data equals 19. 51 with one degree of freedom, this is greater than the critical value of chi squared of 3.84, and the observed distribution can be considered non random, there being an association between the incidence group and ethnic origin of the population.

# 2.5.3 COMPARISON OF STANDARDIZED INCIDENCE RATES OVER A

#### **TWENTY YEAR PERIOD**

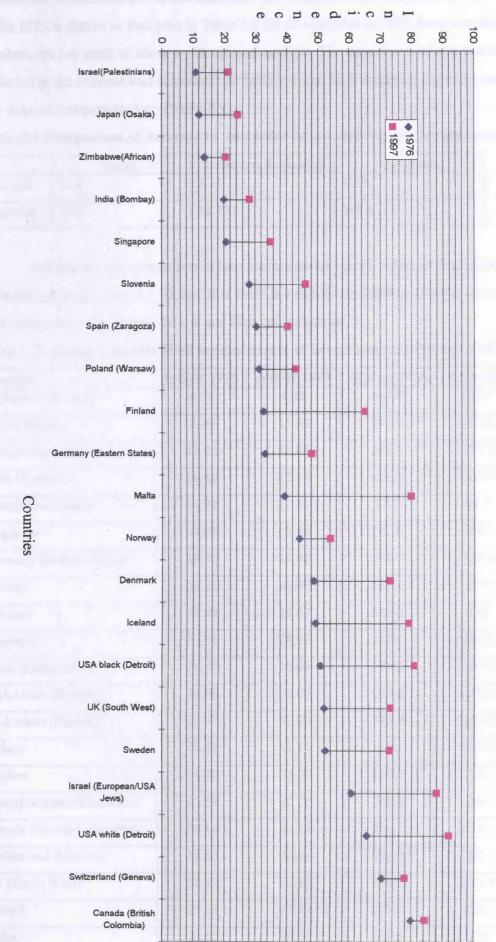

Table 2.8 Standardised incidence rates for breast cancer in 1976 and 1997

Based on the median value for each data set the low or high incidence group is indicated by the letter (L) or (H).

| Country                    | 1976     | 1997    | difference |
|----------------------------|----------|---------|------------|
| Zimbabwe(African)          | 13.8 (L) | 20.4(L) | 6.6        |
| Israel(Palestinians)       | 11(L)    | 21.3(L) | 10.3       |
| Japan (Osaka)              | 12.1(L)  | 24.3(L) | 12.2       |
| India (Bombay)             | 20.1(L)  | 28.2(L) | 8.1        |
| Singapore                  | 20.8(L)  | 35.1(L) | 14.3       |
| Spain (Zaragoza)           | 30.6(L)  | 40.4(L) | 9.8        |
| Poland (Warsaw)            | 31.5(H)  | 43.2(L) | 11.7       |
| Slovenia                   | 28.3(L)  | 46.2(L) | 17.9       |
| Germany (Eastern States)   | 33.4(H)  | 48.2(L) | 14.8       |
| Norway                     | 44.4(H)  | 54.2(L) | 9.8        |
| Finland                    | 32.9(H)  | 65(H)   | 32.1       |
| Sweden                     | 52.4(H)  | 72.9(H) | 20.5       |
| UK (South West)            | 52.1(H)  | 73(H)   | 20.9       |
| Denmark                    | 49.1(H)  | 73.3(H) | 24.2       |
| Switzerland (Geneva)       | 70.6(H)  | 77.8(H) | 7.2        |
| Iceland                    | 49.5(H)  | 79(H)   | 29.5       |
| Malta                      | 39.6(H)  | 79.9(H) | 40.3       |
| USA black (Detroit)        | 51(H)    | 80.8(H) | 29.8       |
| Canada (British Colombia)  | 80(H)    | 84.3(H) | 4.3        |
| Israel (European/USA Jews) | 60.8(H)  | 87.9(H) | 27.1       |
| USA white (Detroit)        | 65.7(H)  | 91.9(H) | 26.2       |
| median value               | 31.05    | 65      |            |

N.B. The median in this smaller 1997 data set is different from that in the larger 1997 data set shown in Table 2.5 where the median is 43.6.

Table 2.8 shows a clear rise in the median value of incidence between 1976 and 1997. Figure 2.9 was plotted from the table and appears to show a greater increase in incidence in the high incidence countries than in the low incidence countries. The

78

Fig 2.9 Changes in breast cancer incidence in selected countries 1976 - 1997

distribution of countries of African and Asian low incidence and European high incidence in the 1976 is similar to that seen in Table 2.5 for all countries in 1997, however the numbers are too small to allow a chi squared analysis. The mean increase and standard variation in the increase was calculated for both low and high incidence countries and a Z test done to compare the two (Table 2.9).

|           | mean | Standard deviation | variance |
|-----------|------|--------------------|----------|
| low risk  | 11.4 | 3.38               | 11.4     |
| high risk | 23.8 | 10.49              | 110.1    |

Table 2.9 Comparison of increase in incidence in low and high incidence countries

A Z test for the comparison of two means resulted in a Z value of 3.67, greater than the critical Z value of 1.96, and that there is a significant difference in the increase in incidence seen in this sample of low and high risk countries.

| Country                   | relSIR 1976 | relSIR 1997 | all sites 1976 | all sites1997 |
|---------------------------|-------------|-------------|----------------|---------------|
| Zimbabwe(African)         | 9.36        | 8.80        | 147.4          | 231.9         |

| Iceland                   | 21.65       | 37.18       | 228.6          | 212.5         |
| Malta                     | 29.60       | 39.55       | 133.8          | 202           |

Table 2.10 Relative standardised incidence rate of breast cancer 1976 and 1997

Graphs were plotted from the data in Table 2.10 to illustrate the standardised incidence of cancer for all sites 1976 and 1997 (Fig 2.10), and the changes in relSIR for breast cancer between 1976 and 1997 (Fig 2.11).

The standardised incidence of cancer for all sites shows varying degrees of increase in all countries except Iceland and Canada (British Colombia). Iceland however, together with Finland and Malta, shows a marked increase in the relative proportionate burden of breast cancer when the rel SIR is considered. Apart from Switzerland, Canada (British Columbia), USA white (Detroit), Norway, and Zimbabwe (African) which show relatively little increase in relSIR, all other countries show a similar rise in the relative proportionate burden of breast cancer.

# 2.5.4 AGE SPECIFIC INCIDENCE OF BREAST CANCER IN SELECTED COUNTRIES WITH RESPECT TO THEIR LEVEL OF INCIDENCE

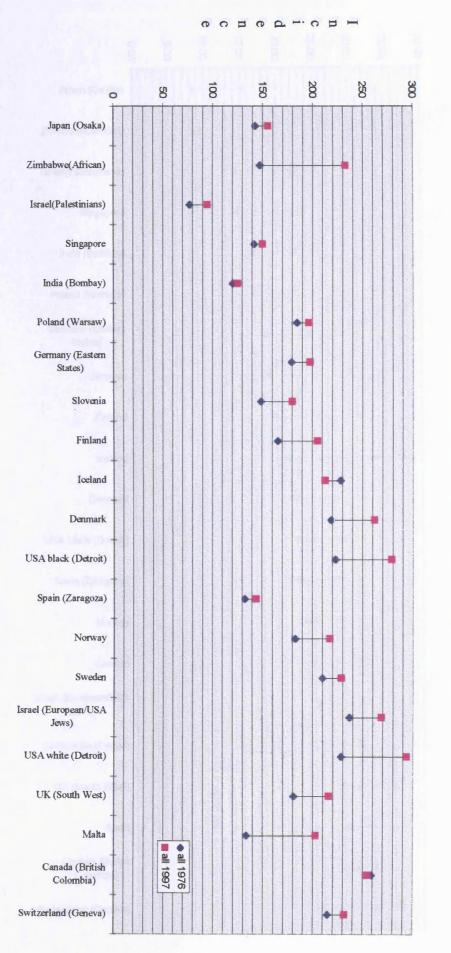

Using the full range of countries from the 1997 data a log ASIR against age Fig 2.12a was plotted, the lines being coloured according to the level of breast cancer incidence, high incidence dark blue, and low incidence red. When more than one registry existed the registry with the standardised rate closest to the mean value was chosen. Figure 2.12a shows the complete set of curves for 1997, including three very irregular curves towards the bottom of the graph, shown in pink. These were identified as being for Mali, Korea, and Algeria; it was decided to omit these from subsequent calculations (see discussion). The data was replotted (Fig 2.12b) without these three data sets.

The ASIR curve for low incidence countries is lower than that of the high incidence countries throughout the age range except before the age of 27 years when the ASIR for low incidence countries is either equal to or more than that in the high incidence countries. The low and high incidence curves are approximately parallel until the 30-35 year old age group when there is an inflexion of the low incidence curves at about 30-40, where as a similar inflexion of the high incidence curves does not occur until 40-50 years of age. This difference results in the subsequent diversion of the two sets of lines.

| countries           | mean age of<br>onset (years) | Z test<br>score | <b>result</b><br>critical Z value = 1.96 |
|---------------------|------------------------------|-----------------|--|
| high incidence vs   | 55.99                        | 1.25            | no significant difference                |
| low incidence       | 50.84                        |                 |  |
| top 10 incidence vs | 56.24                        | 2.07            | significant difference                   |
| bottom 10 incidence | 48.7                         |                 |  |

| T-L1- 1 11  | Maam age  | - f +      | . <b>h</b> 'aib and lam |                    |

| I adie 2.11 | viean age | of onset h | i nign and iow          | v incidence groups |
|             |           |            |                         | monute groups      |

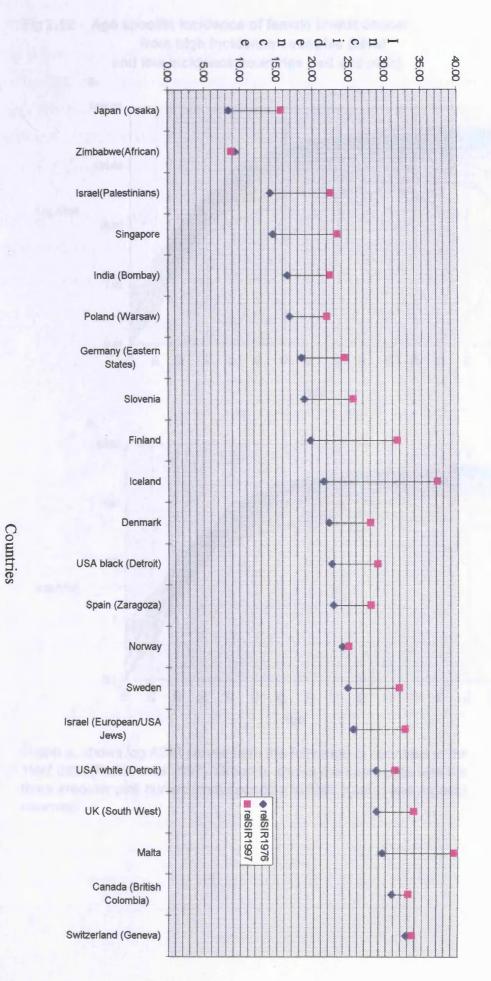

80

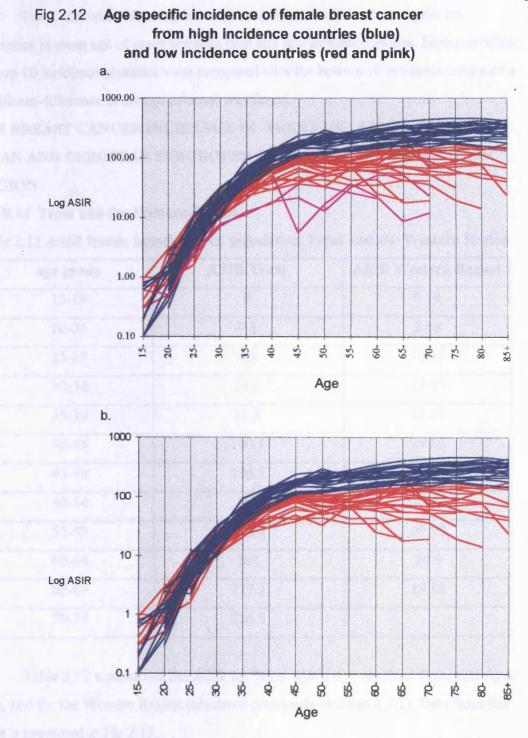

Countries

Fig 2.10 Standardised incidence cancer all sites in selected countries 1976 - 1997

81

Graph a. shows log ASIR curves from the full range of countries in the 1997 data (Parkin et al 1997). Graph b. shows the same data with the three irregular pink curves (corresponding to Mali, Korea, and Algeria) removed.

The Z test when all countries were considered failed to show significant difference in mean age of onset between high and low incidence groups. However when the top 10 incidence countries were compared with the bottom 10 incidence countries a significant difference in the age of onset was found.

# 2.5.5 BREAST CANCER INCIDENCE IN TRENT UK, LEICESTERSHIRE ASIAN AND EUROPEAN SUBGROUPS OF TRENT, AND THE WESTERN REGION

#### ASIR of Trent and the Western Region

Table 2.12 ASIR female breast cancer population Trent and the Western Region

| age group | ASIR Trent | ASIR Western Region |
|-----------|------------|---------------------|
| 15-19     | 0          | 0.18                |

Table 2.12 summarises the ASIR for Trent which was obtained from published data, and for the Western Region calculated previously (section 2.5.1). Data from this table is presented in Fig 2.13.

#### ASIR of the Leicester Asian population

Table 2.13 shows the ASIR of breast cancer in the Leicester Asian population increases steeply to reach a peak at 45-49 years of age, after which there is a decline rising again after the age of 55-59 to reach possibly a second peak at 60-65 year old age group. There were no reported cases younger than 25 years of age. The data from table 2.13 is represented graphically in Figure 2.13.

| age group | no. females | no. breast<br>cancer | ASIR(5 years) | ASIR   |
|-----------|-------------|----------------------|---------------|--------|
| 25-29     | 3708        | 2                    | 53.94         | 10.79  |

| 50-54     | 20898       | 126               | 602.93       | 301.46 |
| 55-59     | 19994       | 92                | 460.14       | 230.07 |
| 60-64     | 20697       | 90                | 434.85       | 217.42 |
| 65-69     | 20480       | 78                | 380.86       | 190.43 |
| 70-74     | 17070       | 72                | 421.79       | 210.90 |
| 75-79     | 15573       | 56                | 359.60       | 179.80 |
| 80+       | 20569       | 66                | 320.87       | 160.44 |

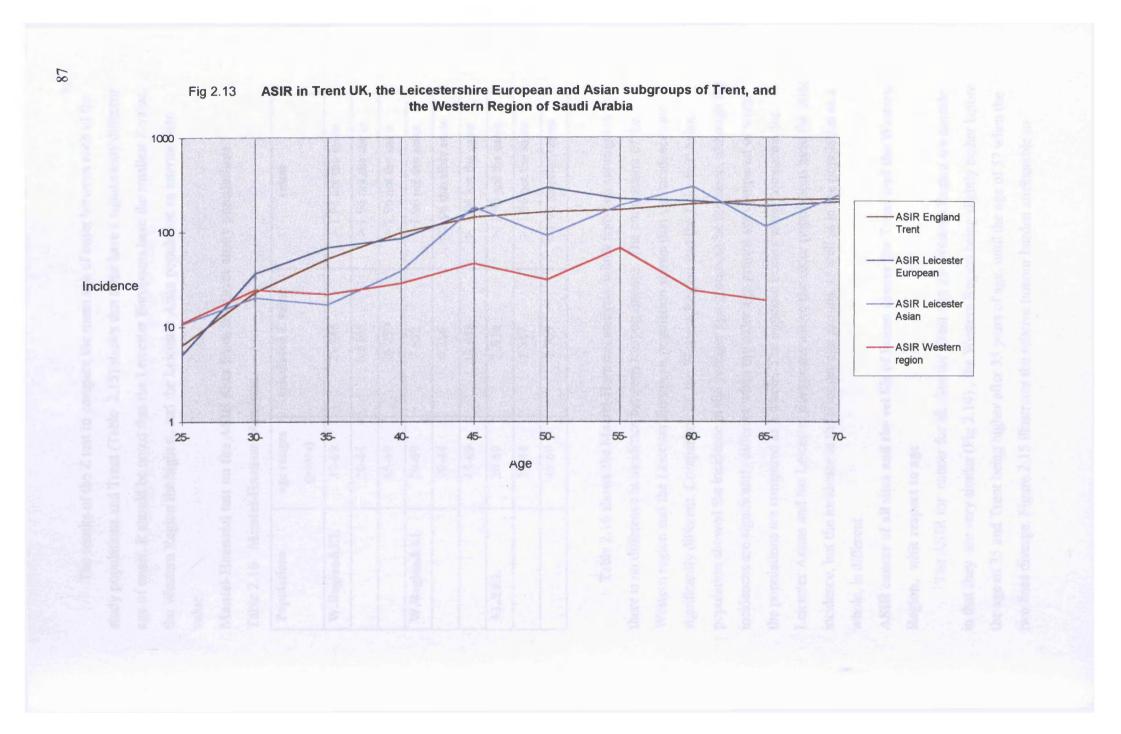

The ASIR of breast cancer in the Leicester European population increases steeply to reach a peak at 50-54 years, after which there is a gradual decline rising again slightly in the 70-74 year old age group. There were no reported cases younger than 25 years of age. The data from table 2.14 is represented graphically in Fig 2.13.

# Comparison of ASIR in Trent UK, the Leicestershire Asian and European subgroups of Trent and with the Western Region

Figure 2.13 shows a graphical comparison of all three populations with that of Trent region. The ASIR curve for Trent rises steadily until the 45-49 year old age group after which the rate of increase lessens until a peak at 65-69 years. The Leicester European population has an ASIR curve which closely follows that of Trent except in the 30-39 year and 50-55 year age ranges when the incidence is notably higher than that of Trent, and even higher than both AL and AA groups. Generally the curve rises to a peak at 50-55 years and then gradually declines. The ASIR of the Asian population however is somewhat different. With the exception of the very young age group, the incidence is always less than that for Trent rising slowly from 25-40 years and then sharply to peak at 45-49 years of age. After this age the curve is somewhat erratic with possible peaks at 60-65 and 70-75 years of age but the general tendency is one of gradual increase. The ASIR of the Western Region is higher than that of Trent from 15 -30 years of age and after that is lower. The ASIR rises most steeply at 17-22 years of age after which the rate drops slightly but continues to rise steadily until the 35-39 years old age group when a sharp drop in the rate of increase occurs, the point of inflexion of the curve described by Clemmesen. The curve then continues to rise, with some fluctuation, at this lower rate until a maximum ASIR is reached at the age 55-59 years, after which the ASIR decreases continually to the 65+ age group. The ASIR curves for the Western Region and for the Leicester Asian population increase at a similar rate until the 40-45 year old age group when the lines cross and diverge, the Leicester Asian population ASIR curve having a general rate of increase similar to that of Trent after the 45-49 years old age group.

| Populations          | Z test results  |  |
|----------------------|---|--|
| (mean age, variance) |   |  |
| Trent (56.7,114.6)   | Z = 0.65 < 1.96 the critical test value at 95% confidence |  |
| vs AA (45.9,165.9)   | no significant difference of mean age of onset            |  |
| Trent (56.7,114.6)   | Z=0.35 < 1.96 the critical test value at 95% confidence   |  |
| vs AL (50.93, 156.5) | no significant difference of mean age of onset            |  |
| Trent (56.7,114.6)   | Z=0.009 < 1.96 the critical test value at 95% confidence  |  |
| vs EL (56.9, 145.5)  | no significant difference of mean age of onset            |  |

| Table 2.15 | Z test to | compare mean | age of | onset |
|------------|-----------|--------------|--------|-------|
|------------|-----------|--------------|--------|-------|

The results of the Z test to compare the mean age of onset between each of the study populations and Trent (Table 2.15) shows that none have a significantly different age of onset. It should be noted that the Leicester Europeans have the smallest Z value, the Western Region the highest, and the Leicester Asian population an intermediate value.

|   | 20-44      | 6.8105             | > 1.96 not the same   |
| <u></u>                                     | 45-69      | 26.259             | > 1.96 not the same   |
| W.Region&AL                                 | 20-69      | 7.652              | > 1.96 not the same   |
|   | 20-44      | 0.236              | < 1.96 therefore same |
| *. /*// <u></u> /////////////////////////// | 45-69      | 10.888             | > 1.96 not the same   |
| AL&EL                                       | 20-69      | 2916               | > 1.96 not the same   |
|   | 20-44      | 2.857              | > 1.96 not the same   |
|   | 45-69      | 1.705              | < 1.96 therefore same |

Table 2.16 shows the Mantel-Haenszel analysis, which tests the assumption that there is no difference in incidence between the populations. The comparison of the Western region and the Leicester European population shows that the incidences are significantly different. Comparison of the Western Region and the Leicester Asian population showed the incidence in the younger age groups to be the same, although the incidences are significantly different when the older age groups are compared or when the populations are compared as a whole. The opposite occurs when comparing the Leicester Asians and the Leicester Europeans where the older populations have the same incidence, but the incidence in the younger age groups, as well as in the population as a whole, is different.

# ASIR cancer of all sites and the rel Sir of breast cancer for Trent and the Western Region, with respect to age

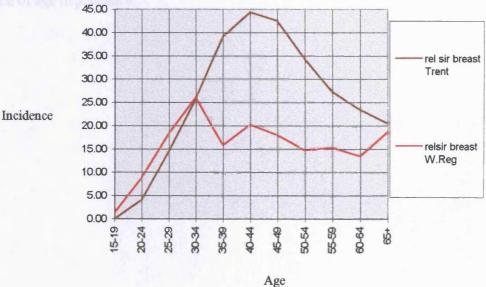

The ASIR for cancer for all sites for Trent and the Western Region are notable in that they are very similar (Fig 2.14), the Western Region being slightly higher before the age of 35 and Trent being higher after 35 years of age, until the age of 57 when the two lines diverge. Figure 2.15 illustrates the relative tumour burden attributable to

# Fig 2.14 ASIR for cancer for all sites for Trent and the Western Region

Fig 2.15

relSIR for female breast cancer for Trent and the Western Region

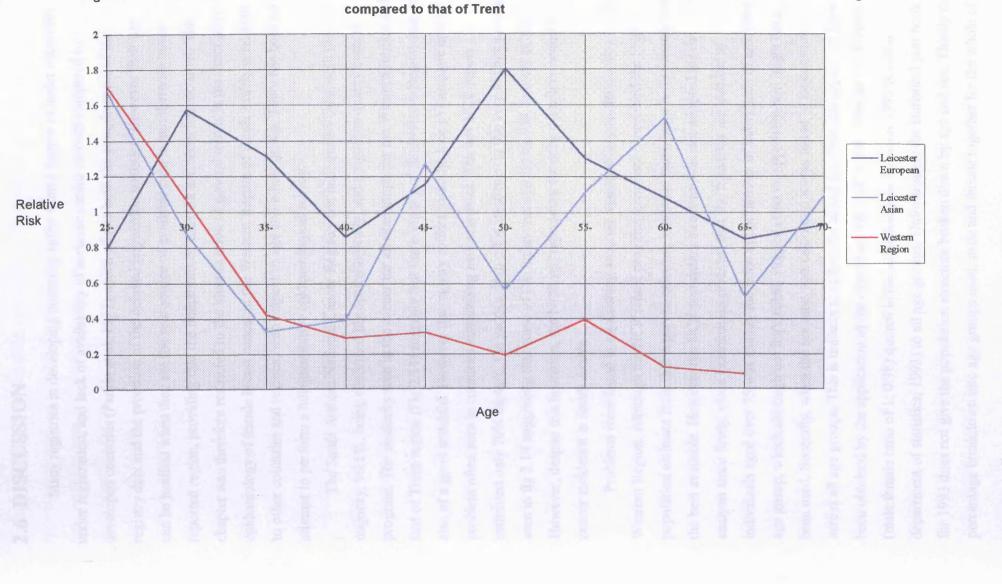

breast carcinoma in different age groups in Trent and the Western Region. In Trent there is a steady rise in relSIR to a peak at 42 years of age and then a slightly slower decline. The Western region shows a similar increase, but to a lower extent, which peaks at 32 years and then shows a much slower, slightly irregular, decline, possibly rising again towards the 65+ age group.

# 2.5.6 AGE SPECIFIC RELATIVE RISK OF BREAST CANCER OF THE THREE STUDY POPULATIONS COMPARED TO THE BREAST CANCER POPULATION IN TRENT

Figure 2.16 shows the relative risk of breast cancer for the Leicester European population compared with Trent having no clear pattern of variation with age, there being a slight excess in risk at 30-34 and 50-55 years of age. Both the Western Region population and the Leicester Asians show greater variation in relative risk of breast cancer when compared to Trent. The relative risk of breast cancer in the Western region is initially higher than that of Trent but exhibits a lower level of risk after the age of 30-34 years. The reduction in relative risk compared to Trent appears to relate approximately with age, apart from a slight elevation in risk at the 55-59 age group. The relative risk of breast cancer for the Leicester Asian population also declines almost directly with age until the 45-49 year age group when relative risk rises almost to one; after that the relative risk approximates to a constant level just below one with no evidence of age dependence.

# Fig 2.16 Relative risk of breast cancer in Leicester Asian and European populations and the population of the Western Region compared to that of Trent

## 2.6 DISCUSSION

Many registries in developing countries suffer from a degree of under diagnosis, under registration, and lack of availability of accurate census records compared to developed countries (Parkin et al, 1997) which affects both the completeness of the registry data and the precision of the detailed population statistics. However their use can be justified when they are the sole source of available data in an otherwise under reported region, providing that the limitations of the data are taken into account. This chapter was therefore restricted to the identification of general trends in the descriptive epidemiology of female breast cancer in the Western Region of Saudi Arabia in relation to other countries and regions, with respect to age and ethnic group. There has been no attempt to perform a full quantitative epidemiological survey.

The Saudi Arabian National Cancer Registry has high quality data, with the majority, 96.1%, being confirmed histopathologically, and a rigorous quality control program. The similarity seen in the cancer for all sites graph for the Western Region and that of Trent region (Fig 2.14) suggests that the accuracy of the Western Region data, is also of a good standard. However the registry suffers from the lack of complete data a problem often seen in countries establishing new registries. The last NCR report estimated only 70% capture, the sudden drop off in incidence in the very old age groups seen in fig 2.14 suggesting that some of this under registration may be in these groups. However, despite this limitation, the NCR still represents the most complete record of cancer incidence in Saudi Arabia.

Problems were found in establishing accurate age specific population data for the Western Region. Although the NCR report provides such data I only used the total population estimate from that report to calculate incidence rates, since it was found to be the best available. However the NCR population structure was not adopted for the analysis since firstly, close examination revealed that the figure for the number of individuals aged over 75 was exactly the same as the number of individuals of unknown age group, which although not impossible, suggests that an approximation might have been used. Secondly, when the sex ratio was calculated it was found to be constant across all age groups. This is unlikely to reflect the actual situation and appears to have been obtained by the application of the overall sex ratio of 50.5% male: 49.5% females (male:female ratio of 1: 0.98) quoted in the statistical year book for 1993 (Central department of statistics, 1993) to all age groups. Unfortunately the statistical year book for 1993 does not give the population structure broken down by age and sex. Thirdly the percentage breakdown into age groups used, male and female together for the whole of

Saudi Arabia, was from the 1974 census, a rather old document. In preference to these figures the population structure for the Makkah region from the 1977 population census was taken and applied to the population figure for the Western region calculated from the crude incidence rate quoted in the NCR report, and the known number of cases (table 2.4). Although this report was not much more recent than the 1974 census, Makkah is geographically close to Jeddah and both are part of the Makkah reporting region (figs 2.4, 2.5) and so is preferable to more generalised national data. In addition the quality of the data was known to be of a good standard, and nothing more recent was available.

The ASIR for the Western Region breast cancer population (Fig 2.13) shows the initial inflection at 35-39 year age group which is much earlier than the classical Clemmesens Hook seen in Western populations and resembles that described by De Waard for oriental populations. The maximum incidence appears to be reached at the 50-55 year age group and then declines. The standardised incidence rate for breast cancer was calculated to be 14.9/100,000 female population; age and incidence are both much lower than those occurring in the West e.g. England and Wales which has a standardised incidence of 72.7/100,000 female population with the incidence peaking in the 60-64 age range and then continuing to climb slowly (the world population being used as the standard for both cases). The pattern of breast cancer in Saudi Arabia therefore appears to be different from that seen in the West both in terms of overall incidence and in age specific incidence.

The fact that geographical differences exist in the incidence of breast cancer is well documented. De Waard (1979) described Far Eastern populations as having "Oriental" type, and North American and North Europeans as having "Western" type with Eastern and Southern European, Latin American and African populations having an intermediate pattern of disease. In De Waards study, due probably to the data available, Asian countries were restricted to Japan, Taiwan, and Singapore. African data was also of limited availability. In the present study representative registries from all African, Asian, European and North American countries published in Parkin et al (1997) were included, with the exception of the Zimbabwe white population. This population had an extremely high incidence of breast cancer, and after consideration of the notes given in Parkin et al which indicated probable artefacts due to low population numbers it was decided to exclude it from the analysis, to avoid skewing the data in favour of the hypothesis. The analysis revealed that the difference in incidence observed between low incidence and high incidence countries was significant (table 2.6) and that the geographical distribution

of low and high incidence countries was not random (table2.7), there being a tendency for Asian and African countries to have a low incidence of breast cancer and Mediterranean and European (including North American whites) to have a high incidence. It was noted that the Eastern European countries appear to be equally distributed about the median (five in the low incidence group and four in the high incidence group). This study confirms that the geographical variation reported using earlier data (De Waard, 1979; Kelsey and Horn-Ross, 1993; Gilliland, 1997) still exists and is statistically significant, despite the reported increase in breast cancer in developing countries during recent years (Kelsey and Horn-Ross, 1993; Patavino et al, 1995) and that it can be demonstrated in the countries selected. The non random assortment of countries into regions of high, intermediate and low incidence breast cancer risk by geographical region and the continuous distribution from low to high incidence (Fig2.8) suggests the possibility of a gradient of breast cancer incidence which is related to geographic location.

The results presented also show that there has been little change in the geographical composition of low incidence and high incidence countries during the twenty year period. There is still a common tendency for Asian and African countries to have a low incidence and Northern American and Northern European and Mediterranean countries to have a high incidence. Breast cancer has been reported to be increasing in all countries for which data is available (Wang et al, 1998) and countries studied here also showed this trend. However the findings for the change in standardised incidence rates over a twenty year period (Fig 2.9) shows that although the increase is seen in most of the countries, there is significantly a greater increase in those countries which already had a high incidence of breast cancer (table 2.9). This contrasts with the findings of Kelsey and Horn-Ross (1993) and Patavino et al (1995) who reported the greatest increase to be in low incidence countries but agrees with the findings of Stephens (1997). Possible explanations for this difference may be the selection of countries, and the time span selected for comparison. I concentrated on countries in Europe, Africa, and Asia (with the addition of the North American black and white communities who are considered to be of African and European descent) and excluded those countries from South America and the Pacific Region which were included in the paper by Kelsey and Horn-Ross (1993). The time period quoted in Patavino et al (1995) of 1950 - 1988 is also different from the 1977 to 1997 which I used.

In order to understand the temporal changes observed, cancer incidence for all sites was examined for 1977 and 1997 for the same group of countries (Fig 2.10). All

the countries, during this period, showed an increased incidence of cancer at all sites with the exception of Iceland and Canada (British Colombia); particularly large increases were shown by Malta and Zimbabwe. Using the incidence values for cancer at all sites and the incidence values for breast cancer it is possible to calculate the relSIR for breast cancer, this being a measure of the relative tumour burden in a population attributable to breast carcinoma. The relSIR for breast carcinoma (Fig 2.11) was examined over the twenty year period from 1977 -1997 in relation to cancer incidence for all sites. All countries showed an increase of relSIR for breast carcinoma with the exception of Zimbabwe (African) which exhibited a very small decrease. The notable increase in the incidence of breast cancer in Finland during this period has been attributed (Gastrin, 1980) to the establishment of mammographic screening. The increase in relSIR for breast carcinoma seen in Iceland however is probably attributable to the overall decrease in cancer incidence at all sites thus increasing the relative tumour burden due to breast carcinoma. Malta however exhibits a large increase both in cancer incidence at all sites and in relSIR, although the latter is less than that seen for Finland or Iceland, which could indicate overall improvement of cancer awareness and diagnostic methods.

Increase in relSIR appears to vary throughout the incidence range of countries, suggesting that this might be a general phenomenon even in regions experiencing only a moderate increase in standardised incidence of breast carcinoma (fig 2.9) such as the low incidence countries of Asia and Africa, although the extent to which the increase is due to an increase of breast cancer or a reduction of other cancers may vary from country to country.

Epigenetic explanations for the world wide increase in breast cancer mainly relate it to an increased exposure to oestrogen, due to:

changes in reproductive behaviour (e.g. tendencies for an older age at the birth of the first child, and reduced breast feeding)

diet, the intake of food substances of high calorific value result in weight gain and an increase in risk of breast cancer.

Another factor possibly contributing to the rise observed in high incidence countries (which correspond primarily to developed countries of the Western world) is increased detection due to mammographic screening. Since breast cancer has a natural progression of several years screening may discover asymptomatic lesions which may not have presented within the life span of the patient. Such findings could result in an overall increase in incidence in post menopausal breast cancer.

Reproductive factors which decrease oestrogen exposure have been shown to give a reduced risk of breast cancer through out the life time (Manton and Stallard, 1980). The effects in Asian populations are similar to those for European populations and are not enough to explain ethnic differences (Wu et al, 1996a). Incidence in Asian populations being modified by diet has a firmer biological foundation and tofu consumption probably accounts for at least some of the lower incidence of breast cancer seen in the far east and Indian sub-continent. However it can not account for the low incidence seen in the Middle East, or the relatively low levels of breast cancer seen in Southern and Eastern Europe since tofu is not part of the basic diet. Similarly olive oil might contribute to the lower incidence of breast cancer in Southern Europe and the Levant but not for the rest of the Middle East or the Far East. In regions of the former and overlapping into the Indian sub continent there is widespread, almost daily use of turmeric and consumption of a range of legumous plants not traditionally found in the diets of Northern Europe. Such a diet would probably be high in curcumoids and flavenoids, both compounds believed to influence the risk of breast cancer. In some Indian dishes there may even be an enhanced effect caused by the synergistic combination of tofu with turmeric. Turmeric, although not such a major part of Far Eastern cooking is a major ingredient of traditional herbal remedies such as those used in Indonesia. There appear to be protective dietary overlapping 'foot-prints' stretching from the Far East to the Mediterranean: Tofu from the Far East to the Indian sub continent, legumes and turmeric from the sub continent to the Middle East, and olive oil and legumes in the Mediterranean.

The age of mean onset analysis performed enabled a comparison to be made of the mean age of the patient presenting with breast cancer in the different countries. When the entire range of low and high risk countries were analysed the mean age of onset of a patient presenting with breast cancer in low incidence countries was not found to be significantly different than that for patients from high incidence countries. However when the ten countries with the highest incidence were compared with the ten countries with the lowest incidence then the mean age of onset was found to be significantly younger (table 2.11).

Analysis of total incidence will not determine whether there are age specific variations in incidence between different geographic locations. Comparing the ASIR of the different populations however solves this problem. Since breast cancer is rare before the age of 15 and the peak in incidence is reached before the age of 75 years in both high and low incidence countries a truncated range was chosen of 12 age groups from 15

years to 75 years (when available) in five year periods and ASIR studied within these limits. The data from as many countries as possible was pooled (fig 2.12) to help reduce the effect of fluctuations from individual registries due to cohort effect or registration practices and to allow general trends in the ASIR of high and low incidence countries to become apparent.

The log incidence vs. age plot of different populations should result in parallel lines if the populations have the same change in incidence with respect to age, with the curves only varying from each other by a proportionality factor (the relative risk) which is constant for all age groups. However figure 2.12 shows two slightly divergent groups of lines. It can be concluded that there is a tendency for ASIR of breast cancer in countries with a low and high incidence to vary with respect to age, the low incidence countries having a higher incidence before the age of 30 years and an increasingly lower incidence after the age of 45 years. The pattern in these countries is a possible explanation for the apparently contradictory results presented in the studies of Jewish migrants and their descendants (Steinitz et al, 1989; Iscovich and Parkin, 1998). In a study (Iscovich and Parkin, 1998) of a young age group, 0-29 years, of 3<sup>rd</sup> generation Israelis of Asian descent the rate of breast cancer was much higher than in the previous study by Steinitz et al (1989) of first generation Asian immigrants aged 0-75+ years. An alternative explanation is that this difference is due to environmental risk factors brought about by changes in life style. Neither of these explanations can be confirmed or excluded until the 3<sup>rd</sup> generation Israeli cohort reach 75+ years of age. Differences in ASIR curves for breast carcinoma in individual countries have been explained by cohort effect (Moolgavkar et al, 1979; Tarone and Chu, 1992). Although the differences in exposure to external risk factors experienced by individual cohorts within a population will introduce fluctuations in the shape of the ASIR curve, there appears to be a degree of uniformity of shape attributable according to whether the country has high or low incidence (fig 2.12). For fluctuations in environmental risk factors to cause the observed changes in relative synchrony there would be either:

i. a range of different risk factors leading to similar changes, or

ii. a smaller number of risk factors affecting all the populations studied. Evidence from dietary studies shows that certain foods may lower the risk of breast cancer and so the overall incidence, but gives no evidence to account for the apparent differences in ASIR of high and low incidence countries.

The two study regions for this project, Trent UK and the Western Region of Saudi Arabia, are located in high (Northern Europe) and low (Asia) regions of breast

cancer incidence and so serve as a case study for a comparative analysis of the pattern of breast cancer incidence between regions of different incidence. A comparison of the ASIRs for female breast cancer in Trent and the Western Region (fig2.13) show that there is higher incidence in the Western Region than in Trent until the age of 30-35 years, after which the converse is true. The ASIR curves for cancer for all sites for the two regions (fig 2.14) show close similarity, there only being a slight excess in incidence in the Western Region before 30 years of age. The ASIR curve for the Western Region after the age of 40 years is slightly erratic; this may be due to actual differences relating to cohort effects or an be an artefact of age registration. The overall curve is slightly divergent from that of Trent until after the age of 60 years when a marked decrease in incidence occurs. This decrease in incidence over the age of 60 years may again be actual, or due to cohort effects; but more likely is related to, at least in part, under registration in the older age groups.

The relSIRs of the Trent and Western Region present two very different situations (fig 2.15), although under the age of 35 years, the relative tumour burden for breast cancer is similar with only a slight excess in the Western Region. It is interesting to note that the peak relSIR for the Western Region and Trent for the 30-34 year age group is the same. For the oldest age group of 65+ years there is again a common relSIR for breast cancer (although figures related to older age groups and in particularly open ended categories must be treated with caution). The graph indicates that the difference in tumour burden attributable to breast cancer in the Western Region compared to Trent comprises two components, firstly an excess of incidence in the under 35 years and a marked decrease of incidence at over 39 years of age. Also of note is the finding that the graph for the Trent Region shows a peak relSIR at 40-44 years indicating that this is the age group where the tumour burden attributable to breast is at its greatest and not at the age of 65+ years when the incidence is greatest. If alternative approaches to mammographic screening could be found which had a high efficacy in this age group or younger, with a view to detecting breast cancer in the in situ or even possibly premalignant stage, then even a modest reduction in the cases of breast cancer would result in a significant improvement in the total tumour burden of this age group.

Trent contains a sub group of British Asians; by utilising the data from Leicestershire (Fig 2.6) a sub region located within Trent, it was possible to consider European and Asian patients separately and compare them to that of the Western Region and Trent. Z tests comparing the mean age of onset (table 2.15) shows that none are significantly different from that of Trent although the difference was greatest for the

Western Region and least for the Leicester Europeans. Comparison of the ASIR curves for breast cancer for the four populations (Trent, Leicester Europeans, Leicester Asians, and Western Region) (fig 2.13) shows the Leicester European population follows closest that of Trent. This is to be expected since the majority population in Trent is European. The ASIR for breast cancer for the Western Region is higher that that of Trent under the age of 30, but after that age has a lower incidence. The curve for the Leicester Asian population appears to have two phases, following closely the curve for the Western Region until the 45-49 age group, after which it is closer to the curve for the Leicester European population. To compare the differences in incidence between the Leicester European, the Leicester Asian and Western region populations Mantel-Haenszel analysis was performed, which tests the assumption that there is no difference in incidence (table 2.16). Because the ASIR curves for the Leicester Asian population differed whether under or over 45 years, 20-44 year and 45-69 year ranges were considered as well as 20-69 years.

The incidences for the age range from 20-69 years showed the three populations to be significantly different, with the biggest difference being between the ASIR for the Western Region and the Leicester European population. This concurs with the study of Winter et al (1999) who found the incidence of breast cancer in the S.Asian UK population to be 46.6 compared with 72.9 in the non-Asian population, which would place the S.Asian population in the low incidence group and the non Asian in the high incidence group as defined for this thesis (sections 2.4.2 and 2.5.2). When the younger (20-44years) and older (45-69 years) age groups for the Western Region and the Leicester European populations were analysed the incidences were significantly different for both groups. However the Leicester Asian population was found to have no significant difference in incidence in the 20-44 year age range when compared to the Western Region population, and no significant difference in incidence in the 45-69 year age range when compared to the Leicester European population, confirming the statistical significance of the observations made from fig 2.13.

The age specific relative risk of the three study populations using Trent as a standard was also compared (fig 2.16). There appears to be a greater relative risk of breast cancer in the Leicester European population compared to Trent in the 30-34 years and 50-54 year age groups. Whether this is a reflection of population differences or a transient feature is not addressed here but warrants further study. The Western Region has a relative risk higher than Trent in the under 30 year olds, but a much lower risk after the age of 35. An interesting feature of the graph is how the relative risk of the Leicester

Asian populations follows closely to that of the Western Region population until the 40-44 age group after which it is closer to that of Trent. It was not possible to compare the three study populations with the S.Asian study group of Winter et al (1999) since detailed 5 yearly ASIR data was not provided. However they did find that although the overall incidence of breast cancer was lower in S.Asians, young S.Asians (under 29 years) had a higher incidence of breast cancer than their non Asian counterparts. This is not inconsistent with the results found in my research.

I have already discussed that reproductive factors and obesity are unlikely to have an effect on premenopausal breast cancer. However there may be similarities in the diet of Western Region and Leicester Asians which may be relevant, and there is evidence that these dietary factors lower the overall risk of breast cancer. There appear to be ethnic differences in breast cancer incidence which cannot be fully explained by known environmental risk factors, and there is the possibility that this may be due to a genetic component (Chaudary et al, 1991; Davis et al, 1995; Trock et al, 1996).

Since the Leicester Asian population is closer genetically to the population of the Western Region than to that of the Leicester European population and yet experiences an environment (although not necessarily diet) similar to the Leicester European population, the pattern invites the speculation that breast cancer under the age of 44 years is dominated by genetic components and after this age environmental risk factors, for example those related to reproduction and weight gain become important.

The observation that the excess of very young cases appears to be a robust characteristic of low incidence countries being evident even in immigrant populations that have moved to a Westernised high incidence environment, adds weight to the argument for a significant role of genetic predisposition in this group.

I have demonstrated graphically in this chapter differences in the ASIR curves, with low incidence countries having an earlier point of inflexion (Clemmesens hook) than high incidence countries, in the populations studied. This is in addition to the apparent difference in the age of onset of breast cancer patients between those populations.

The De Lisi (1977) model requires a fixed position of Clemmesens hook and Moolgavkar (1980) makes no allowance for differences in ASIR, considering observed ethnic differences to be due to cohort effect. It is therefore proposed that the study presents data which is not inconsistent with the model of Manton and Stallard (derived from the de Waard model) that breast cancer comprises two diseases, one

the proportion of pre menopausal type and post menopausal type cases of breast cancer present in the population.

# CHAPTER THREE

# COMPARISON OF MARKERS OF TUMOUR BEHAVIOUR WITH REFERENCE TO AGE AND ETHNICITY IN THE THREE STUDY POPULATIONS

## **3.1 INTRODUCTION**

Aggressive is an adjective frequently utilised in papers describing the behaviour of breast cancer in Saudi Arabia (Al Idrissi et al, 1992) and some other low risk countries e.g. Egypt (Richards et al, 1992), Kuwait (Motawy et al, 1994). Some publications suggest that there may be underlying biological differences between ethnic groups (Huang et al, 1995; Hartmann et al, 1996). Breast tumours in the Indian sub continent are reported to be of early onset and late stage (Hussain et al, 1994; Goel et al, 1995), but whether this is due solely to the limitations of public health education and facilities, or to the aggressive nature of the tumour has not been studied. The British Asian breast cancer population are also at low risk for breast cancer, but full details on survival, disease free interval etc. are still limited for the minority ethnic groups in the United Kingdom. In the United States early age at onset, irrespective of ethnic origin, has also been associated with aggressive tumours and poorer prognosis (Fowble, 1994).

#### **3.1.1 TUMOUR BEHAVIOUR**

Differences in the relative behaviour of breast tumours have been described between different ethnic groups, and between age groups.

#### **Ethnic variation**

Generally Black Americans (AmB), Hispanic Americans (AmH), and Asian Americans (AmA) present at a younger age, higher stage and have more extensive lymph node involvement than American Whites (AmW) (Aziz et al, 1999; Boyer-Chammard et al, 1999). Krieger et al (1997), comparing AmA, AmW, and AmB, found that AmA and AmB have more tumours over the size of 2cm, independent of socio-economic status. In addition AmB have been reported as having lower survival rate within each stage, which cannot entirely be accounted for by delay in diagnosis (Vernon et al, 1985). Edwards et al (1998) in a large study of 115,838 patients comparing race, age and stage found that the ratio of regional disease to localised disease decreased with age in AmW, but remained approximately constant in AmB. They concluded that age and race had a significant association with tumour stage and an independent impact on survival. This appears to be present even when there is equal access to health facilities as in a study by Wojcik et al (1998) in the US Military. Wojcik's study found AmB had a younger age of onset of breast cancer, and even when this was adjusted for still had a worse survival than AmW. Similar results were found in other studies (Hunter et al, 1993; Eley et al, 1994) so socio-economic differences are not the only explanation.

Ijaduola and Smith (1998) found both AmB and West African women (WAf) present with breast cancer at a later stage and larger tumour size than AmW. Hassan et

al (1992), also noted an excess of young WAf patients with a much lower than expected survival rate and postulated that this was due not only to the delayed presentation of the patients and lack of efficient treatment regimes but also to the aggressive nature of the tumours.

The differences in presentation and course of disease therefore appear to indicate ethnic variation in the biological nature of breast cancer (Newman and Alfonso, 1997), although this is disputed by some (Weiss et al, 1995; El-Tamer et al, 1999; Yood et al, 1999).

#### Age related variation

Several studies have found a young age at diagnosis to be an independent negative prognostic factor (Aaltomaa et al, 1992a; de la Rochefordiere et al, 1993; Nixon et al, 1994), including studies from Saudi Arabia (Al Idrissi et al, 1992; Ezzat et al, 1998). Younger breast cancer patients have been reported to have a higher proportion of grade three tumours (Walker et al, 1996; Gillett et al, 1997; Fisher et al, 1997) a generally poorer prognosis irrespective of grade (Albain et al, 1994; Chung et al, 1996), and more frequent occurrence of lymph node involvement, even when compared with tumours of the same size in postmenopausal women (Peer et al, 1996; Gillett et al, 1997).

Kollias et al (1997), concluded that the worse prognosis for breast cancer in the young was due to the higher proportion of poorly differentiated tumours and not directly attributable to age, Azzat et al.(1999) describing breast cancer cases in Saudi Arabia made a similar conclusion. Bertheau et al (1999), though considered that breast cancer in young women often has the features of high grade malignancy, even if some have good survival, and that young breast cancer is different. Generally young, premenopausal, breast cancer is associated with markers associated with aggressive, less well differentiated tumours (section 1.4.5 Devilee/Walker model) including overexpression of erbB2 (Allred et al, 1992), and higher modal chromosome number (Pandis et al, 1996). These studies provide support to the proposal that premenopausal breast cancer may be biologically different to post menopausal breast cancer.

It is apparent that heterogeneity also exists in the biological nature of breast cancer within the premenopausal age group. Walker et al (1996) found tumours occurring in patients under 35 year old to more poorly differentiated, have higher rates of proliferation, and more frequently p53 positive than tumours in premenopausal patients aged over 35 years. Patients under 30 years also had a lower incidence of ER and PgR positive tumours. The majority of cases were sporadic (18% of the 35-44 years age

group and 11% of the under 30 years age group reported a family history of breast cancer). However some studies have failed to find a poorer prognosis or evidence of a more aggressive tumour type in these younger premenopausal breast cancer patients (Anderson et al, 1995; Sariego et al, 1995; Sananes et al, 1996), finding breast cancer in the older age group to be an equally aggressive disease (Hakama and Rihimaki, 1974). Others describe young breast cancer as an aggressive disease but quote a more favourable long term prognosis for these patients (Gillett et al, 1997). These apparently contradictory results may be attributable to differences in methodology and classification, or may simply reflect the heterogeneous nature of the disease.

The higher incidence of larger tumours may partly be explained by the reluctance or inability of certain ethnic groups to obtain prompt medical attention. There is also the tendency of some clinicians not to suspect malignancy when presented with a breast lump in a patient under 35 years of age (Menon et al, 1992). However the majority of studies indicate that young patients and certain ethnic groups have a higher than expected risk of developing high grade aggressive tumours (Velentgas and Daling, 1994) and there is increasing evidence for the existence of actual biological differences in the tumours of these groups.

#### **3.1.2 INDICATORS OF TUMOUR BEHAVIOUR**

The disease free interval (DFI) and overall survival reflects the biological dynamic characteristics of the tumour providing similar treatment protocols are followed. In the absence of adequate patient follow up data to compare survival or disease free interval in the study populations, this chapter seeks to use histopathological tumour data, and nuclear morphometric characteristics as surrogate markers of tumour behaviour.

#### **Stage of Disease**

TNM, which comprises tumour size, lymph node involvement and presence of distant metastasis, gives information about the extent of invasion spread and is of prognostic value (section 1.4.1). Generally the further the progression, the worse the prognosis, with the presence of distant metastases being a sign of advanced systemic disease. However the TNM stage alone gives a rather static picture of the existing state of affairs and not the full picture of the biological nature of the tumour and its aggressiveness.

#### **Tumour Size**

A larger tumour size is associated with an increased incidence of node involvement and distant metastasis (Koscielny et al, 1989). However a proportion of

small tumours (<1.0cm), as reported by Carter et al (1989), may have a lower survival rate than some larger tumours with the same extent of lymph node involvement.

#### **Node Status**

Generally lymph node negative patients have a better prognosis than lymph node positive patients, however 20-30% of lymph node negative patients still go on to develop metastases within the first 10 years. This may indicate a subset of more aggressive tumours (Sears et al, 1982), or the presence of occult metastases not revealed by routine examination.

#### Histopathological grade

The histopathological grade, comprising tubule formation, mitotic activity, and pleomorphism of cells (section 1.4.1), is known to be of prognostic significance in breast cancer (Elston and Ellis, 1991). Grade has been shown to be a prognostic factor for long term tumour behaviour (Elston and Ellis, 1991), as well as for overall survival independent of lymph node status (Davis et al, 1986; Contesso et al, 1989). In post menopausal patients grade has been shown to exert influence on the outcome of adjuvant therapy (Contesso et al, 1989). Henson et al (1991) described cases where, within each TNM grouping, grade was related to survival irrespective of lymph node status, e.g. patients with grade 1 tumours had a consistent survival advantage even in stage IV disease.

#### **Prognostic indices**

The use of histopathological and biological markers can help differentiate TNM stages into prognostic groups by providing information about the biological nature of the tumour (Baak et al, 1985).

Two documented prognostic indices are:

1. The Nottingham Prognostic Index, NPI, was formulated for patients with primary breast carcinoma based on those factors that influenced prognosis. Nine prognostic factors were analysed retrospectively and after appropriate weightings from multivariate analysis the following formula was derived:

NPI=0.2 x tumour size (cm) + lymph node stage (1-3) + histological grade (1-3) NPI scores maybe categorised: <3.4 good prognosis. 3.4 -5.4 moderate prognosis, and >5.4 poor prognosis (Pinder et al, 1995). NPI has successfully been used to differentiate patients with good prognosis (80% 15 year survival), moderate prognosis (42% 15 year survival), and poor prognosis (13% 15 year survival) (Galea et al, 1992).

2. The Yorkshire Breast Cancer Group (YBCG) used similar methods to derive a modified prognostic index YBCGPI (Brown et al, 1993):

YBCGPI = 0.1 x clinical tumour size (cm)+ 0.5 grade score + 0.6 nodal involvement

Using this equation it is possible to group patients into three prognostic groups (good < 1.21, moderate 1.21 > 1.82 and poor > 1.82). The YBCGPI and the NPI show close correlation when Kaplan-Meier survival curves are plotted for the prognostic groups (Brown et al, 1993).

#### **3.1.3 QUANTITATIVE MICROSCOPY**

Quantitative techniques have the advantage of greater reproducibility and objectivity than qualitative judgements, and may reveal differences in comparative studies, not readily identified by qualitative description (Baak and Oort, 1983).

#### **Tumour Fraction**

#### Measurement

Percentage of tumour area or volume (a/A or Vv) occupied by invasive tumour cells is required for the calculation of the volume corrected mitotic index VMI. It also gives a measure of cellularity and has been termed cellularity mean index CMI (Ambros and Trost, 1990)

Applying the principals of Delesse (1847), the average area of any component of the tissue on a histological slide will be proportional to its volume:

 $V_v = A_A$ 

However Delesse assumes that  $A_A$  is a constant through out the sample and therefore identical in each section, as would be the case of a cube with a face parallel to the cut surface. Since nuclei approximate to spheres this assumption does not hold true. Instead it is necessary to use an alternative estimator of volume fraction derived by Mayhew and Cruz-Orive (1974).

 $V_v = a/A$ 

a is the mean area of the component being measured

A is the mean area of the surrounding area.

The fractional areas (A and a) may be estimated directly from the microscope using an eye piece graticule and by point counting (Ahearne and Dunhill, 1987), (section 3.4.2). *Prognostic value* 

Ambros and Trost (1990) found CMI (Vv) to correlate to lymph node involvement and VMI, and to indicate poor prognosis. A study by van Diest et al (1992) concluded that CMI was a good prognosticator of the response to adjuvant chemo therapy in pre menopausal lymph node positive patients.

#### **Mitotic index**

#### **Reproducibility**

The reproducibility of the components of histopathological grade, including the mitotic count, have often been questioned (Dufer et al, 1993), but if strict criteria are adhered to, good inter observer correlation can be obtained (Frierson et al, 1995).

There are two potential sources of variation when making quantitative mitotic counts, associated with:

#### Counting methodology:

It is necessary to strictly define the selection of the area on the slide to be counted, the method of counting, and what constitutes a scorable mitotic figure. In choosing the area it is important as far as possible to avoid selection bias. Baak and Oort (1983) summarised the optimal sampling procedure:

Mitotic figures should be scored in the area showing most mitotic activity.

10 fields should be counted at random within the area.

The mitotic index is conventionally taken as the number of mitotic figures per 10 high power fields selected from the most cellular area of the tumour (Baak et al, 1985). Robbins et al (1995) suggested that by counting fours groups of 10 high power fields and recording the highest mitotic score adds to the reproducibility of the counting procedure. However this method does not allow for differences in tumour cellularity, cell size, nor size of the high power field of the particular microscope. These differences can be standardised by measuring the ratio of the number of mitoses to the number of malignant cells (Ellis and Whitehead, 1981; Simpson et al, 1992). If the ratio of mitoses per tumour volume, the volume corrected mitotic index M/V, is measured this will also allow for variation in the thickness of sections (Haapasalo et al, 1989). M/V has the same prognostic value as the mitotic index (Jannink et al, 1996), and the advantage of increased reproducibility, especially important when comparing samples from different institutions.

Whatever counting method is chosen only definite mitotic figures should be counted, Baak and Oort (1983) suggested certain criteria to ensure that pyknotic nuclei are not included:

The nuclear membrane must be absent, and either a distinct stage of mitosis should be recognisable or the 'hairy' projections of the chromosomes visible. The latter contrasts with pyknotic or deformed nuclei that tend to appear 'spiky'.

#### ii. Stability of mitotic figures

Delay in fixation may affect mitotic count by decreasing the number of mitotic figures, since during the delay it is possible for dividing cells to complete their cycle of division (Bullough, 1950). Bergers et al (1997) found that although a delay prior to fixation decreases the quality of the section the number of identifiable mitotic figures and reproducibility was not affected.

#### Prognostic value

The mitotic frequency has been found in several papers to be a significant independent parameter for prognosis (Biesterfeld et al, 1995; Laderkal and Jensen, 1995) particularly the risk of recurrence (Aaltomaa et al, 1992b). The volume corrected mitotic index (m/v) allows identification of patients with poorer prognosis among ER+ve tumours (Aaltomaa et al, 1991). The number of mitotic figures and nuclear atypia were strongly correlated with the copy number of c-erbB-2, an independent prognostic factor associated with poor prognosis and aggressive tumours (Heintz et al, 1990; Tsuda et al, 1990).

#### Nuclear morphometry

#### **Measurements**

The function of nuclear morphometry, or planimetry, is to derive descriptive statistics of populations of tumour nuclei from two - dimensional measurements. Any nucleus in a histological section will appear approximately circular, but even if all the nuclei were uniformly sized spheres these circles would vary in size according to the point of sectioning (fig 3.1). The thickness of a histological section is less than the diameter of the tumour nuclei being studied, and so all nuclei within the section will be transected, this being at random. Hence then the mean size and standard variation in dimensions of the resulting circles will be dependent upon the size of the population of nuclei from which they were cut. Also, measurements that rely on quotients or ratios (shape and ratio of axis) should remain relatively constant for all the sections of the nucleus.

#### Reproducibility

The main sources of error when making morphological measurements of nuclei can be attributed to:

i. Selection of nuclei:

Baak et al (1982) suggested using microphotographs taken at 1000 x magnification randomly in the most cellular area of the tumour and measuring 25-50 nuclei, whereas

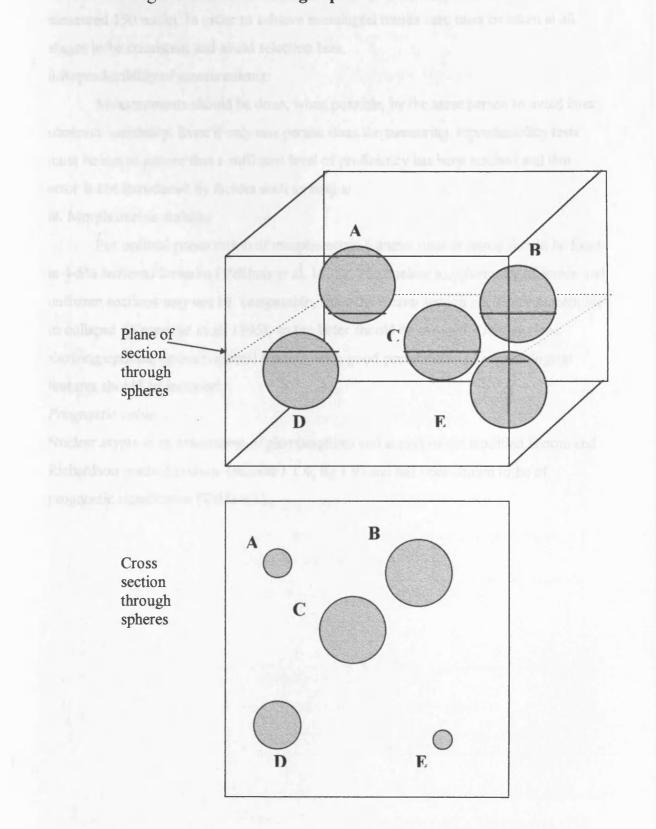

Fig 3.1 Sections through spheres in a theoretical matrix

Pienta and Coffey (1991) selected 30 fields at random from across the specimen and measured 150 nuclei. In order to achieve meaningful results care must be taken at all stages to be consistent and avoid selection bias.

ii.Reproducibility of measurements:

Measurements should be done, when possible, by the same person to avoid inter observer variability. Even if only one person does the measuring, reproducibility tests must be run to ensure that a sufficient level of proficiency has been reached and that error is not introduced by factors such as fatigue.

#### iii. Morphometric stability

For optimal preservation of morphometric features tumour tissue should be fixed in 4-5% buffered formalin (Velthuis et al, 1978). The nuclear morphometry of frozen and unfrozen sections may not be comparable, since the frozen section nuclei are susceptible to collapse (Kronqvist et al, 1995), so the latter should be avoided. Only sections showing optimal, or near optimal fixation, with good preservation of morphological features should be included.

#### Prognostic value

Nuclear atypia is an assessment of pleomorphism and is part of the modified Bloom and Richardson grading system (section 1.1.4, fig 1.9) and has been shown to be of prognostic significance (Table 3.1).

# Table 3.1: The prognostic significance of selected morphometric measurements

| Measurement                 | Research findings   |
|-----------------------------|---|
| standard deviation of       | independant prognostic value <sup>a</sup> and a predictor of  |
| nuclear perimeter           | DFI <sup>b</sup>  |
| (SDNP)                      |   |
| mean nuclear area           | Significant prognostic factor <sup>e</sup>                    |
| (NA)                        | correlated to higher rate of proliferation <sup>d</sup>       |
| intra sample varience of    | node +ve pts marked increase in VNA compared to               |
| nuclear area                | node -ve <sup>e</sup>   |
| (VNA)                       |   |
| standard deviation of       | predicts DFI in young node positive patients <sup>b</sup>     |
| nuclear area (SDNA)         |   |
| nuclear area for the 10     | predicts survival and DFI in young node -ve                   |

## **3.2 AIMS**

The aims of this chapter are to:

Assess if any differences in the potential biological behaviour of tumours from the three study populations could be detected by use of chosen prognostic indicators.

Determine if any differences found could be attributed to age or ethnic origin .

### **3.3 MATERIALS**

#### **3.3.1 PATIENT AND TUMOUR DATA**

#### Jeddah study group (AA)

A total of 198 breast cancer patients with invasive carcinomas were identified in five major hospitals in Jeddah, to form the AA study group. Ethnic origin and age of the patient, tumour size, type, and grade, and the number of lymph nodes examined plus the number involved by metastasis, was extracted manually from pathology records for three hospitals (149 patients). At the remaining two hospitals (50 patients) a computer search was made and the required patient and tumour data copied.

#### Leicester European (EL) and Leicester Asian (AL) study groups.

Two groups of Leicestershire patients, 78 EL and 42 AL, were identified from either a database of patients compiled by Dr Rosemary Walker, or from the computerised records of the Leicestershire Pathology Service. Data was provided about age, tumour size, tumour type, grade, and lymph node status (including number of total lymph nodes involved).

#### Complete patient and tumour data.

This comprised:

Patient data: the name or ethnic group and age.

Tumour data: type, grade, size, lymph node status and number of affected lymph nodes.

#### Minimum patient and tumour data.

This was at least the ethnic group and age of the patient and the type of the tumour. Although not all cases had complete patient and tumour data, cases were considered for inclusion if at least minimal patient and tumour data was available.

#### **3.3.2 TISSUES**

All tissues had been fixed in formal-saline (4% formaldehyde/saline) and processed through to paraffin wax. The samples from the hospitals in Jeddah comprised specimens that had been immersion fixed for periods of time which could not be determined from the records, prior to selection of blocks for processing. In the review of material by Dr. Walker only blocks with adequate preservation were selected. Samples that had been frozen prior to fixation were avoided for morphometric work.

All of the specimens from Europeans in Leicestershire had been received fresh, and samples of tumour selected, generally no more than  $2.0 \times 1.5 \times 0.5$  cm, for fixation for 18-24 hrs prior to processing. Approximately half of the tissues from Asians in Leicestershire had been treated in the same way, while the rest consisted of specimens which had been immersion fixed for 18-48 hrs prior to selection of the tumour blocks.

#### **3.4 METHODS**

#### **3.4.1 COMPILATION OF THE STUDY GROUPS**

# Comparison of the Saudi and non Saudi female breast cancer populations in the Western region

Although for the ASIR calculations for the Western Region in Chapter two only Saudi patients were considered, the NCR contains data on both Saudi and non-Saudi patients, the nationality of all individuals being included.

Inclusion of the non-Saudis would provide a larger pool of cases for study. Therefore a comparison was made to find if there is a significant difference in the ages of Saudi and non Saudi female breast cancer patients in the Western Region, or whether they could statistically considered to be elements of the same population with respect to age. A t-test was performed between Saudi and non-Saudi cases over the truncated age range of 20 -65 years (see discussion). A Z-test was performed to compare the two patient populations to determine if the mean age of onset varied significantly between the two.

Patients were only selected for the AA study group if they were Saudi nationals or nationals of low incidence countries sharing a similar ethnic background as the Saudi population (section 2.1.5.).

# Investigation of the Jeddah data as a sub group of the Western Region tumour registry data

The detailed data for the Saudi study group came from 5 major hospitals in Jeddah. The age distribution of this study group was statistically compared with that of the Western Region database to test whether it is a representative sample.

The age data for the Jeddah database and the Western Region Tumour Registry were subjected to a t-test to investigate whether the Jeddah data base can be considered a statistically representative sub-group of the Western Region Tumour Registry female breast cancer population, with respect to age.

# Selection of the Leicestershire European (EL) and Leicestershire Asian (AL) study groups

The European patients were selected from patients diagnosed between 1993 and 1995 by Dr Walker, and were age matched with the Saudi groups for whom both data and samples were available. The Leicester Asian group, due to the relatively low incidence and smaller overall population, were selected from a wider time span (1983 -1997) in order to collect sufficient cases and included all suitable available cases. For both EL and AL cases with impalpable tumours diagnosed by mammographic screening were excluded, since no such routine service is available in the Western Region.

#### Comparison of the three study groups and data encoding

After selection of AA, AL, and EL cases t - tests were performed to test for any significant difference in age between these three groups.

Once collected the data was coded according to ethnic origin (AA, AL, or EL) age at diagnosis, and source, and given an identification number.

#### 3.4.2 CLINICO-BIOLOGICAL CHARACTERISTICS

Haematoxylin and eosin stained sections of all cases collected from hospitals in Jeddah were reviewed by Dr Rosemary Walker for pathological type, using the classification detailed in the NHS BSP Pathology Reporting Guidelines 2<sup>nd</sup> edition (1995), and for histological grade using the modification of the Bloom and Richardson grading system (Elston and Ellis, 1991) (See 1.4.1 Fig 1.9). The same classification and grading system was used for all cases from Leicestershire. All tumours selected were Infiltrating Ductal (IDC) of no special type or had a major IDC component. Patient and tumour data were analysed for the three study groups (Saudi Asians, Leicester Asians, Leicester Europeans)

In addition two prognostic indexes were calculated for those cases where sufficient information was available:

i. The Nottingham Prognostic Index (NPI) (Galea et al, 1992; Pinder et al, 1995)

NPI = 0.2 x tumour size(cm) + lymph node stage(1-3) + histological grade(1-3) where no affected lymph nodes equals lymph node stage 1, 3 or less involved lymph nodes stage 2, and 4 or more axillary lymph nodes and/or internal mammary lymph nodes involved, stage 3.

ii. Yorkshire Breast Cancer Group Prognostic Index (YBCGPI) (Brown et al, 1993) which is

YBCGPI = 0.1 x clinical tumour size + 0.5 grade score + 0.6 nodal involvement (1 or 3) Where grade score equals 1 for the modified Bloom and Richardson grade 1 and 2 for grades 2 or 3, and lymph node involvement equals 1 for LN -ve and 3 for LN+ve. Statistics

For the *continuous* variables the mean, variation, standard deviation and coefficient of variation was calculated for each of the study groups. Variation within a study group between tumours from patients under and over 44 years of age, and also those from pre and post menopausal patients was assessed using t-tests, two tailed assuming unequal variance, for each of the study groups. Menopause was taken as occurring at 50 years (Morabia and Costarza, 1998).

Each study group was sorted according to age and the mean value for each variable or PI (prognostic index ) was calculated for each age. The variable or PI was then plotted for:

i. Yearly age intervals

ii. Seven selected age groups :

20-29 years
30-39 years
40-44 years
45-49 years
50-54 years
55-59 years
60-69 years

To assist comparison of trends between the different graphs polynomic trend lines were inserted using the trend line facility in Excell 7. A comparison was then made between pairs of study groups, the following age ranges were tested by means of t-tests, two tailed assuming unequal variance:

i. Entire age range

- ii. Pre menopausal (less than 50 years of age)
- iii. Post menopausal (more than or equal to 50 years of age)
- iv. 44 years or under

v. over 44 years

for AA and EL, AL and AA, and AL and EL.

For the *discrete* variables variation within a study group, between tumours from patients under and over 44 years of age, and between pre and post menopausal patients was assessed using  $\chi^2$  tests, for each of the study groups. A comparison was then made

of the same specified age ranges, as for the continuous variables, between pairs of study groups, by means of  $\chi^2$  tests, i.e. AA and EL, AL and AA, and AL and EL study groups. Some of the categories used contained less than five and so caution was used in interpreting these, the results affected are marked with an asterisk.

#### 3.4.3 MITOTIC INDEX AND TUMOUR FRACTION

#### **Preparation of sections**

 $4\mu m$  sections were cut for 107 breast carcinomas identified from the Saudi Asians, the criterion for selection being the availability of blocks and sufficient material being present within the blocks. These were dewaxed, rehydrated and stained in Mayer's haemotoxylin (1 min) and eosin (10secs), dehydrated and mounted in Xam. Leicester European and Leicester Asian cases were brought from the UK ready cut as  $4\mu m$ sections onto slides and were then prepared in the same way.

#### Calculation of tumour fraction and volume corrected mitotic index

The most cellular area of the section was selected and within this area fields were chosen at random. Prior to relocation to a new field the microscope was defocused slightly. This allowed the selection of the field within the cellular area without the mitotic figures being visible, thus helping to ensure the random nature of the selection and minimise selection bias. The microscope was then brought back into focus and using an ocular graticule (1 mm index grid 19mm x 19mm) counts were made utilising the intersections of the grid. Scores were classified as malignant epithelium or non-epithelium, and counted using a manual haematological cell type counter.

A total of 10 fields were counted and the number of mitotic cells recorded counted according to the recommendations of Baak and Oort (1983). This procedure was repeated for another three groups of 10 fields, a total of 40 fields, and the highest recorded number of mitotic figures used for the calculation of the mitotic index as suggested by Robbins et al (1995).

The volume corrected mitotic index VMI was calculated for each case (Theoretical background given in Section 3.1.3):

• Estimation of tumour volume fraction Vv

 $Vv = \Sigma (P_{epi}) / \Sigma (P_{epi} + P_{conn})$ 

for a total of ten fields.

 $P_{epi}$  is the number of points counted on epithelium and  $P_{conn}$  is the number of points on stroma and other non epithelial structures.

Calculation of volume corrected mitotic index

M/Vv index (VMI) =  $k \Sigma MI / \Sigma Vv$ 

MI is the number of mitotic figures, Vv the volume fraction estimated by Aa expressed as a percentage, and k is the fields constant equal to  $100/\pi r^2$  (r being the radius of the microscope field measured in mm). Counts were done using the x40 objective lens.

#### Reproducibility

VMI and the tumour fraction Vv on a series of three samples, one from each study group taken at random, was measured. The same samples were measured again after one month. A paired t-test was performed on the two groups for VMI and Vv. Analysis

The volume corrected mitotic index, VMI, was calculated for each case and mean, variation, standard deviation and coefficient of variation for VMI was calculated for each of the study groups. Variation within a study group between tumours from patients under and over 44 years of age, and also those from pre and post menopausal patients was assessed using t-tests, two tailed assuming unequal varience. A comparison was then made of specified age ranges between pairs of study groups. The following age ranges were tested by means of t-tests, two tailed assuming unequal variance for AA and EL, AL and AA, and AL and EL:

Entire age range Pre menopausal Post menopausal under 44 years over 44 years

#### **3.4.4 NUCLEAR MORPHOMETRY**

#### **Photography**

Microphotographs were taken of the prepared H&E stained tumour sections, using a Zeiss Axiophot photomicroscope at 1000 x magnification under oil, following the guidelines for field selection of Baak and Ort (1983). The most cellular region of the tumour was located at low power. Microphotographs were taken at random within this region; a slight defocusing of the microscope when relocating the field ensured that the field was still within the selected region of highest cellularity but kept the selection of the fields random, avoiding the possibility of observer biased selection. Using Konica VX100 36 exposure colour print film ISO 100/21°, between 3 - 8 microphotographs were taken for each case according to the cellularity of the tumour, a minimum of 100 tumour nuclei per case being recorded. Developing was done commercially using a Konica "Nice Print QSS" developer model 808 (exposure time 2.5 min/picture, set magnification factor of 4.3) to obtain 10 x 15 cm pictures. A 1mm stage micrometer slide was also photographed at x 1000 magnification under oil and subjected to the same processing, for use in calibration.

#### **Image analysis**

The microphotographs for each case were scanned on an Apple flat bed scanner using OFOTO version 2 software (Light Source Computer images inc.1993) and a Macintosh power PC 8100/110. The images were stored in TIFF format and exported to the Public Domain NIH programme version 1.57 (written by Wayne Rasband at the U.S. National Institute of Health, part number PB93-504868). The programme will be referred to as NIH Image.

#### Calibration

The microphotograph of a 1mm stage micrometer slide was scanned into the computer and exported into NIH Image for use in calibration. Within the NIH Image programme the distance between 5 divisions on the scale was measured in pixels. "Set scale" was selected from the "Analyse" menu and the measured length and the equivalent number of pixels entered (in addition to ratio of horizontal to vertical which was set at 1, and the units measured which was set at  $\mu$ m). The resulting scale was 6.9 pixels per  $\mu$ m. in the image.

#### Nuclear measurements

The tumour cells were identified, after instruction from Dr Walker, by their large nuclei, frequently abnormal nuclear shape, chromatin pattern and nucleoli. The densely staining compact stromal fibroblasts, lymphocytes and macrophages were avoided. Using the free hand drawing tool, guided by the mouse, the perimeter of each tumour nucleus was outlined and a macro (written by Dr P Furness Leicester University) was utilised to measure the basic nuclear features (Table3.2). NIH Image has a series of predefined arrays (including area, length, major axis, and minor axis) and two unnamed arrays (user1 and user2) which can used to store macros to record and display derived results

A minimum of 100 nuclei per case were measured (Baak and Oort, 1983). However in the situation where measurement was continued on a new microphotograph image all tumour nuclei on that image were then measured to avoid selection bias. This total was in some cases as high as 150 nuclei.

The nuclear features measured by the NIH Image programme were (fig 3.2):

perimeter area shape factor (4  $\pi$  x area / (perimeter)<sup>2</sup>) shortest axis longest axis ratio of max and min nuclear diameter

## **Reproducibility and specificity**

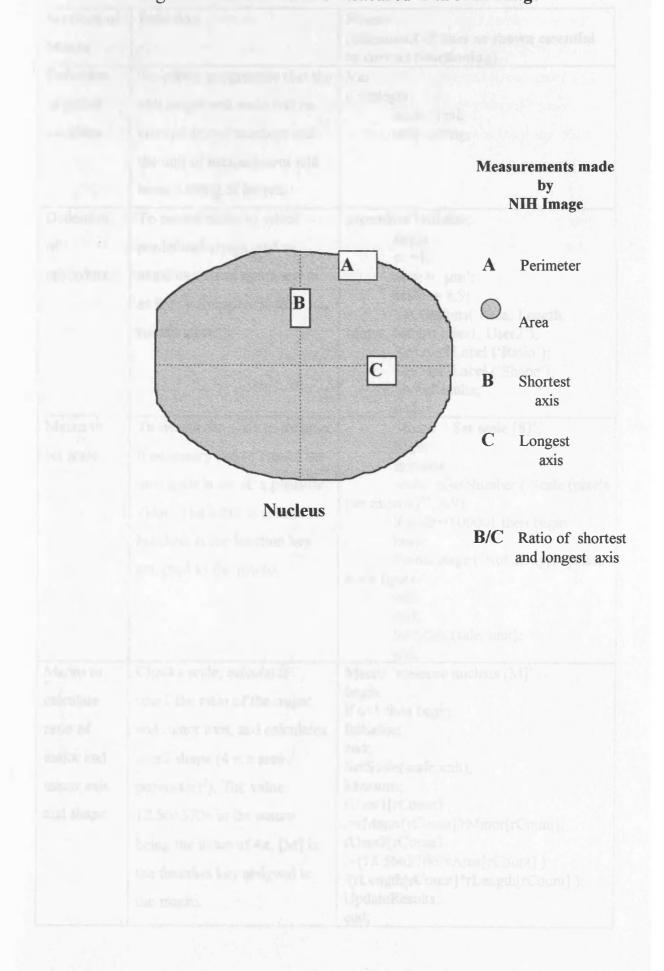

Reproducibility was checked by repeating the nuclear measurements of a set of photographs one week and three months after the first assessment. A t-test was then applied. Specificity was checked by:

- i. Comparing the nuclear measurements of two cases selected at random to test inter tumour variability.
- ii. Comparing the nuclear measurements of two cases selected due to contrasting appearance, to test sensitivity
- iii. Taking twice the number of photographs from an individual case, shuffling the prints and dealing them into two groups. The nuclear measurements of these were then compared, and a t-test applied to test intra tumour variability.

## **Data processing**

Raw data was imported from NIH Image into Excell 7 and the following morphometric measurements calculated, which have been found to be of prognostic value in some studies (Pienta and Coffey, 1991; Eskelinen et al, 1992). (Summary data appendix A).

- a. Standard deviation of the nuclear perimeter (SDNP)
- ii. Mean nuclear area (NA)
- iii. Variance of nuclear area (VNA)
- iv. Standard deviation of nuclear area (SDNA)
- v. Nuclear area for the 10 largest nuclei in the field (NA10)
- vi. Ratio of max and min nuclear diameter (ND1:ND2)
- vii. Max nuclear diameter (Ndmax)
- viii. Shape coefficient (Sh)

Table 3.2 Macro used to measure nuclear features

### Analysis

For each study population the following were calculated and compared; for all ages, at intervals of one year, under and over 44 years, pre and post menopausal and for the seven selected age ranges used previously. Polynomic trend lines were included and used throughout for comparison. T tests were performed to compare the entire age range, under and over 44 years, and pre and post menopausal cases for the three study groups.

#### Morphometric measurements

For each study population, cases were arranged in ascending order according to age and the morphometric measurements tabulated in the summary data plotted against age. AA was plotted twice; once with all available data and again after omission of a single extreme result (see discussion).

i.Variation in the nuclear area

The coefficient of variation and the difference between the coefficient for the under 44 and over 44 year old groups was calculated for each study population. The results were tabulated.

ii. SDNP, and MeanNDmax.

iii. Mean ratio of maximum to minimum tumour cell diameters (ND1:ND2).

iv.The mean shape

Values of the mean variance, and standard deviation of shape were calculated for the entire age. The coefficient of variation was also calculated for each study population.

# **3.5 RESULTS**

## 3.5.1 NUMBER OF AVAILABLE CASES FOR EACH STUDY

The number of cases available for each study, for each of the study groups is shown in table 3.3

|                | AA  | AL | EL |
|----------------|-----|----|----|
| Total screened | 198 | 42 | 78 |
| Tumour size    | 132 | 35 | 70 |
| LN status      | 151 | 37 | 75 |
| Grade          | 181 | 42 | 78 |
| NPI            | 107 | 34 | 65 |
| YBCGPI         | 110 | 34 | 69 |
| Vv and VMI     | 77  | 39 | 73 |
| Nuclear        | 107 | 41 | 76 |
| Morphometry    |     |    |    |

Table 3.3 Summary of case availability

# 3.5.2 COMPARISON OF THE CRUDE FREQUENCY OF SAUDI AND NON SAUDI FEMALE BREAST CANCER PATIENTS IN THE WESTERN REGION

Data for breast cancer is shown in Table 3.4. Comparison of the values for standard deviation and coefficient of variation for the Saudi and non-Saudi populations are presented in table 3.4. The age of the non Saudi group is more homogeneous than the population of Saudi nationals. A t-test performed on truncated data (see discussion) between the ages of 20 -65 years yielded a t statistic of 0.398 which is less than the critical value of 1.96 at the 95% confidence level and so the Saudi and non-Saudi samples can be considered as coming from a single population with respect to age.

|                          | Saudi | Non-Saudi |
|--------------------------|-------|-----------|
| mean age                 | 46.56 | 44.3      |
| standard deviation       | 13.9  | 11.62     |
| coefficient of variation | 30.06 | 26.23     |

Table 3.4 Comparison of breast cancer in the Saudi and non Saudi population

The Z-test for the comparison of two means resulted in a Z value of 0.124 which is less than the critical Z value, at a 95% confidence level, of 1.96, and therefore there is no significant difference between the two populations with respect to mean age of onset. In view of this breast cancers from both the Saudi and non-Saudi patients were used in the AA study group.

# 2.5.3 INVESTIGATION OF THE JEDDAH DATA BASE AS A SUB GROUP OF THE WESTERN REGION TUMOUR REGISTRY DATA

Since the data for the Western Region in Chapter two was restricted to only Saudi patients a t-test was performed to assess if there is any significant difference between the Jeddah data (which includes both Saudi and non-Saudis) and the Western Region data with respect to age, table 3.5.

|          | W.Region | Jeddah |
|----------|----------|--------|
| Mean     | 46.92    | 46.90  |
| Variance | 168.43   | 170.82 |
| t Stat   | 0.99     |        |

Table 3.5 t-Test: Two-Sample Assuming Unequal Variances

Since the t statistic is equal to 0.99, for the two tailed test, and is less than the critical value of 1.97 the Jeddah AA group can be considered to be a statistically representative sub group of the Western Region Tumour Registry database with respect to age.

## 3.5.4 CLINICO-BIOLOGICAL CHARACTERISTICS

#### **Tumour size**

The coefficient of variation was calculated for tumour size (table 3.6) for each of the study groups. Over the entire age range the coefficient of variation of the tumour size is less in the AL study group than in the other two groups. The AA study group tended to have a higher mean tumour size than EL, with AL intermediate between the two.

| Table 3.6 Variation in tumour size within the study g | roups |
|---|-------|
|---|-------|

| Study Group | Range (mm) | Mean (mm) | Var       | SD       | Coeff Var |
|-------------|------------|-----------|-----------|----------|-----------|
| AA          | 8 - 130    | 40.93     | 487.59    | 22.08    | 53.95     |
| AL          | 15 - 85    | 34.1      | 254.9     | 15.96    | 46.76     |
| EL          | 10 - 80    | 26.43     | 187.28    | 13.68    | 51.77     |
|             | (10-135)*  | (27.99)*  | (352.94)* | (18.78)* | (67.13)*  |

\* the value in brackets represents the inclusion of one out lying case in EL

The results of t-tests between different age groupings of the same study group, table 3.7., show that there is no significant difference in mean tumour size between pre or post menopausal patients, nor between patients under or over 44 years of age, in any of the study groups.

Table 3.7 Comparison of tumour size within study groups

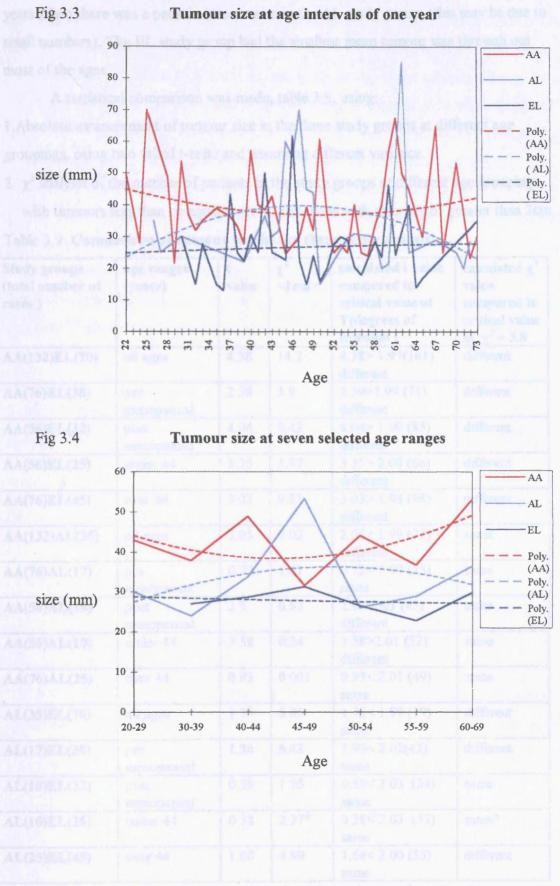

| Study<br>group | Age grouping<br>(% over2cm,<br>number of case)   | t<br>value | χ <sup>2</sup><br><2cm> | calculated t<br>value compared<br>to critical value<br>of t (degrees of<br>freedom) | calculated $\chi^2$<br>value compared<br>to critical value<br>of $\chi^2 = 3.8$ for a<br>2X2 table |
|----------------|--|------------|-------------------------|---|--|

The mean tumour size was calculated for each of the three study groups at age intervals of one year and the resulting values plotted, (figure 3.3). The AA study group tended to have a higher mean tumour size than EL, with AL intermediate between the two. All three study groups showed a marked degree of variation in mean tumour size.

 Table 3.8 Tumour size in the three study groups over seven selected age ranges

NB 95 At least one cell contained less than 5 outries and a fotal less than 40

The data for the seven selected age ranges is shown in Table 3.8 and Fig 3.4. The AA study group had the largest mean tumour size, except between the ages of 45 and 49 years when there was a peak in tumour size in the AL study group, (this may be due to small numbers). The EL study group had the smallest mean tumour size through out most of the ages.

A statistical comparison was made, table 3.9, using:

1. Absolute measurement of tumour size in the three study groups at different age groupings, using two tailed t-tests and assuming different variance.

2.  $\chi^2$  analysis of the number of patients in the study groups at different age groupings

with tumours less than or equal to 2cm, and those with tumours of greater than 2cm.

 Table 3.9 Comparison of tumour size in the three study groups

**NB**\*: At least one cell contained less than 5 entries and a total less than 40

There was a significant difference in the absolute tumour size of the AA study group and the EL study group regardless of the age divisions used. This difference was also significant and independent of age when the number of patients with tumours above and below 2cm were considered.

In the comparison of AA and AL there was no significant difference between the two study groups for any of the age categories when the number of tumours above and below 2cm were analysed. However when tumour size was considered as an absolute measurement there was a significant difference in the under 44 years, and post menopausal groups, and also when the groups were considered as a whole.

When the mean tumour size of the AL and EL study groups were compared there was no significant difference for any of the age groupings considered, where the tumour size was taken as an absolute measurement. However when cases with tumours above and below 2cm were considered there was a significant difference in the pre menopausal and over 44 years old age groupings, and also when the group was considered as a whole.

#### Node status

| Group | % LN +ve<br>cases all ages | % LN +ve<br>cases pre<br>menopausal | % LN +ve<br>cases post<br>menopausal | % LN +ve<br>cases 44 years<br>and under | % LN +ve<br>over 44<br>years |

Table 3.10 Node status for the three study groups

Table 3.10 shows AA to have the highest percentage of lymph node positive cases and EL the lowest, with AL being intermediate. All study groups had more pre menopausal lymph node positive cases than post menopausal, and more cases under 44 years of age than over.

Table 3.11 compares node status within groups and shows that in the EL study group there was no significant difference in node status between pre or post menopausal patients, nor between patients under or over 44 years of age. In the AL study group a significant difference in node status was found when comparing the under and over 44 years age groupings and the pre and post menopausal groupings.

| Study<br>group | Age grouping<br>(total number of cases) | calculated $\chi^2$ | calculated $\chi^2$ value compared<br>to critical value of $\chi^2 = 3.8$ |
|----------------|---|---------------------|---|

| AA(85)AL(26)                               | over 44               | 3.26                         | < same  |
| AL(37)EL(75)                               | all ages              | 1.02                         | < same  |
| AL(17)EL(41)                               | pre menopausal        | 4.87                         | >different  |
| AL(20)EL(34)                               | post menopausal       | 1.07                         | < same  |
| AL(11)EL(25)                               | under 44              | 4.19                         | >different  |
| AL(26)EL(50)                               | over 44               | 0.0002                       | < same  |

Table 3.12 shows that there was a significant difference in node status in all age groupings considered between the AA and EL populations.

A significant difference between AL and AA was only found in the post menopausal age group, although the difference in the over 44 years age group approached significance. Neither of the younger age groupings, under 44 or pre menopausal, showed a significant difference. For AL and EL both of the two younger age groupings were significantly different, whereas all other age groupings showed no significant differences.

# Grade

 $\chi^2$  analysis of grade for all groups at all ages produces a calculated chi value of 24.6, the critical chi value at 4 degrees of freedom being 9.5, indicating that there is significant variation in grade between the three study populations.

The grade ratio published by Elston (1987) (1:2.06:2.5) was used as a standard, the population being geographically close to Leicestershire (Nottingham) and both centres use the same criteria for grade classification; a  $\chi^2$  analysis for goodness of fit was made.

| Table3.13 Number of cases | in each grade categor | y for the three study groups. |
|---------------------------|-----------------------|-------------------------------|
|---------------------------|-----------------------|-------------------------------|

|    | Grade 1 | Grade 2 | Grade 3 | calculated $\chi^2$ value | calculated $\chi^2$ value<br>compared to critical value<br>of $\chi^2 = 5.99$ (2df) |
|----|---------|---------|---------|---------------------------|---|
| AA | 3       | 54      | 124     | 51.69                     | >5.99 different   |
| AL | 4       | 16      | 22      | 2.28                      | <5.99 same  |
| EL | 12      | 31      | 35      | 0.47                      | <5.99 same  |

Table 3.13 shows a significant difference in the ratio of grades present in AA compared to the standard, whereas neither of the Leicester populations show a significant difference.

The results of t-tests between different age groupings of the same study group are presented in table 3.14.

Table 3.14 Comparison of grade III with grades I+II within study groups

| Study<br>group | Age grouping<br>(% of grade 3,total number of cases) | χ²   | calculated $\chi^2$ value<br>compared to critical<br>value of $\chi^2 = 3.8$ |
|----------------|--|------|--|
| AA             | pre(66,111)and post(71,70) menopausal                | 0.45 | < same   |
|                | under(71,85) and over(65,96) 44 years                | 0.78 | < same   |
| AL             | pre(68,23) and post(39,19) menopausal                | 3.58 | < same   |
|                | under(63,11) and over(47, 31) 44 years               | 0.97 | < same   |
| EL             | pre(55,42) and post(34,36) menopausal                | 3.60 | < same   |
| ······         | under (58,26) and over(38,52) 44 years               | 2.59 | < same   |

Because of the limited numbers of grade 1 cases in AA and AL, it was not possible to analyse grades separately; grades 1 and 2 were combined and compared with grade 3, using  $\chi^2$  analysis. None of the study groups showed any significant difference in grade between the age groupings studied, AA having the lowest  $\chi^2$  values, and EL the highest.

| Study groups<br>(total number of<br>cases) | age ranges (years) | $\chi^2$ | calculated $\chi^2$ value<br>compared to critical<br>value of $\chi^2 = 3.8$ |

Table 3.15 Comparison of grade III with grades I+II in the three study groups

Table 3.15 shows that there was a significant difference in the number of patients in the AA and EL populations with grade 3 tumours when all ages were considered, and in the post menopausal and over 44 years old groupings, however there was no difference in the pre menopausal or under 44 groups.

Similarly significant differences were found between AL and AA at all ages and post menopausal groups, with the over 44 year group approaching significance; and again there was no difference the two younger groupings.

No significant difference was found between AL and EL in any of the age groups analysed.

#### **Nottingham Prognostic Index**

|    | Range       | var  | SD   | mean | coefvar |
|----|-------------|------|------|------|---------|
| AA | 3.16 - 8.00 | 1.35 | 1.16 | 5.6  | 20.77   |
| AL | 2.30 - 7.40 | 1.62 | 1.27 | 5.0  | 25.45   |
| EL | 2.20 - 7.70 | 1.68 | 1.3  | 4.55 | 28.47   |

Table 3.16 Variation in NPI within the study groups

Table 3.16 shows the NPI score presented as a continuous variable; the higher the score the worse the prognosis. AA had the highest mean score and EL the lowest, EL has the highest coefficient of variation and AA the lowest.

NPI can be placed into discrete categories of good, moderate and poor prognosis according to score. Scores of NPI according to category are presented in table 3.17.

|  | Table 3.17 | NPI | prognostic | categories |
|--|------------|-----|------------|------------|
|--|------------|-----|------------|------------|

| Prognostic category           | good   | moderate     | poor   |
|-------------------------------|--------|--------------|--------|
| (NPI score range in brackets) | (<3.4) | (3.4 - 5.4 ) | (>5.4) |
| AA                            | 1      | 40           | 66     |
| AL                            | 3      | 14           | 17     |
| EL                            | 14     | 33           | 18     |

All study groups had the least number of cases in the good prognostic group, but AA and AL had more in the poor category whereas most of the EL cases were in the moderate category. A  $\chi^2$  analysis of this data resulted in a chi value of 40.01 which is more than the critical value of chi of 9.5 at 4 degrees of freedom, and thus shows that there was a significant difference in NPI categories between the study groups.

Since there were only a few cases in the good prognostic category in AA and AL it was not possible to analyse each category and age group separately. Instead prognostic categories good and moderate were combined and compared to the poor prognostic category.

Comparison of NPI as a continuous variable and prognostic category within study groups are presented in table 3.18.

Table 3.18 Comparison of NPI within study groups

\*at least one cell less than 5 with the total less than 40

The results show that in all of the study groups there was no significant difference in NPI, calculated as a continuous variable or as a prognostic category, between pre or post menopausal patients, nor between patients under or over 44 years of age, with the exception of the comparison of pre and post menopausal cases in the AL population when NPI was considered as a continuous variable.

The mean NPI was calculated for each of the three study groups at age intervals of one year and the resulting values plotted, (figure 3.5). This shows that the AA study group tended to have a higher NPI than EL. All three study groups showed a marked degree of variation in NPI. Table 3.19 presents the data divided into seven selected age ranges which is plotted in Fig 3.6.

Table 3.19 NPI in the three study groups over seven selected age ranges

| AGE   | NPI AA | NPI AL | NPI EL                                |
|-------|--------|--------|---------------------------------------|
| 20-29 | 5.99   | 6.10   | · · · · · · · · · · · · · · · · · · · |
| 30-39 | 5.47   | 4.98   | 4.75                                  |
| 40-44 | 6.24   | 5.43   | 5.03                                  |

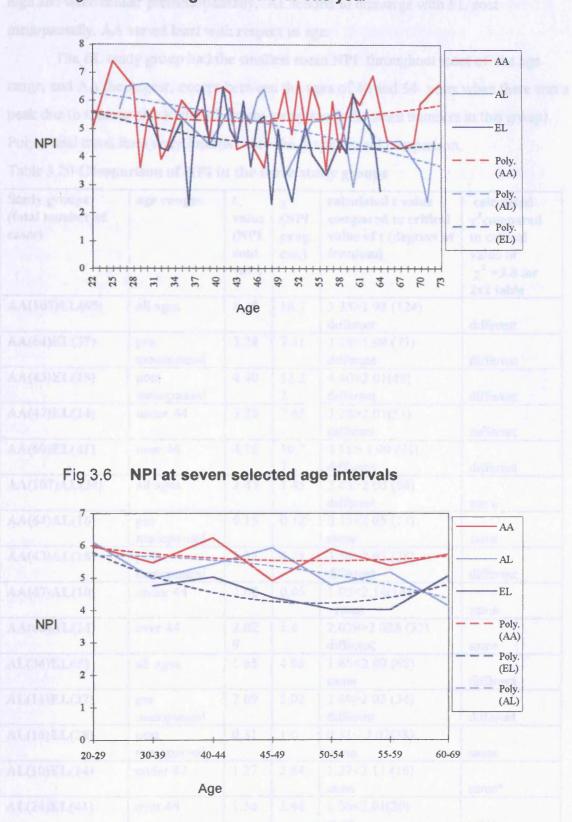

Fig 3.5 NPI at age intervals of one year

"at least one call last then 5 and the total loss that 40

Figure 3.6 shows that NPI was high for all three study groups in the 30 - 39 years age range but then rapidly decreased with age for the EL group. AA and AL remained high and were similar premenopausally, AL tended to converge with EL post menopausally. AA varied least with respect to age.

The EL study group had the smallest mean NPI throughout most of the age range, and AA the largest, except between the ages of 40 and 54 years when there was a peak due to tumour size in the AL study group (note the small numbers in this group). Polynomial trend lines were inserted onto the graphs to aid comparison.

 Table 3.20 Comparison of NPI in the three study groups

\*at least one cell less than 5 and the total less than 40

A statistical comparison was made of NPI in the three study groups at different age groupings, table 3.20.

There was a significant difference in the NPI, both as a continuous variable and prognostic categories, between AA and EL in all of the age groupings.

When prognostic categories of NPI were considered, a significant difference between AA and AL was only found in the post menopausal group. However when NPI was considered as a continuous variable in addition to the post menopausal group the over 44 years and all age groups were also significantly different.

There was no significant difference between AL and EL for under and over 44 years, nor for the post menopausal group. The pre menopausal group however showed a significant difference, similar results being obtained irrespective of the mode of assessment of NPI. However a significant difference was found when comparing AL and EL (all ages) for NPI (prognostic categories) but not for NPI (continuous variable). **Yorkshire Breast Cancer Group Prognostic Index** 

| Table 3.21 Variation in | <b>YBCGPI</b> | within the | study groups |
|-------------------------|---------------|------------|--------------|
|-------------------------|---------------|------------|--------------|

|    | Range     | var  | SD   | mean | coefvar |
|----|-----------|------|------|------|---------|
| AA | 1.68-4.10 | 0.4  | 0.63 | 2.85 | 22.17   |
| AL | 1.25-3.50 | 0.46 | 0.68 | 2.60 | 26.18   |
| EL | 1.20-4.15 | 0.57 | 0.75 | 2.40 | 31.42   |

Table 3.21 shows YBCGPI as a constant variable. The AA study group had the largest mean YBCGPI and the EL group the smallest. The coefficient of variation was the least in AA and highest in EL. Table 3.22 presents the YBCGPI scores as discrete prognostic categories.

Table 3.22 Prognostic categories of YBCGPI

| Prognostic category<br>(YBCGPI score range) | good<br>(<1.21) | moderate<br>(1.21<21.82) | poor<br>(>1.82) |

| AL  | 0               | 5                        | 29              |
| EL  | 1               | 22                       | 46              |

It was not possible to perform a  $\chi^2$  analysis of all three categories separately because some of the cells lacked cases. Although all study groups had most cases in the poor prognostic category it can be seen that there were differences in the ratio of moderate to poor: EL was approximately 1:2, AL 1:6, and AA 1:10. Comparison of YBCGPI as a continuous variable and prognostic categories within study groups is presented in table 3.23.

| Study<br>group | Age grouping<br>(% poor<br>catagory, total<br>number of cases) | t value<br>(YBCG<br>PI cont.<br>var) | χ <sup>2</sup><br>(YBCG<br>PI cont.<br>var) | Calculated t value<br>compared to critical<br>value (degrees of<br>freedom) | Calculated $\chi^2$<br>value compared<br>to critical value<br>of $\chi^2=3.8$ for<br>2x2 table |
|----------------|--|--------------------------------------|---|---|--|
| AA             | pre(88, 64)and<br>post(96,46)<br>menopausal                    | 0.76                                 | 2.15  | 0.76< 1.98 (103)<br>same  | same   |
|                | under (94,47) and<br>over (89,63) 44<br>years                  | 1.24                                 | 0.73  | 1.24< 1.98 (101)<br>same  | same   |

Table 3.23 Comparison of YBCGPI within study groups

 $*\chi^2$  analysis could not be performed in where cells with zero cases were present

Table 3.23 shows that for the AA and EL study groups there was no significant difference between the age groups considered regardless of how YBCGPI was assessed. However when YBCGPI was considered as a continuous variable there was a significant difference between both pre and post menopausal and between under and over 44 year old age groups for AL.

The mean YBCGPI was calculated for each of the three study groups at age intervals of one year and the resulting values plotted, polynomial trend lines were inserted to aid comparison (figure 3.7). The AA study group tended to have a higher YBCGPI than EL, and for AL it tended to be higher in the younger cases and lower in the older.

The data was tabulated into seven selected age ranges, table 3.24 and figure 3.8 plotted.

| AGE   | AA   | AL   | EL   |
|-------|------|------|------|
| 20-29 | 2.78 | 3.10 |      |
| 30-39 | 2.84 | 3.04 | 2.48 |
| 40-44 | 3.19 | 2.84 | 2.54 |
| 45-49 | 2.47 | 2.95 | 2.26 |
| 50-54 | 3.03 | 2.46 | 2.20 |
| 55-59 | 2.73 | 2.61 | 2.26 |
| 60-69 | 3.05 | 2.00 | 2.69 |

Table 3.24 YBCGPI in the three study groups over seven selected age ranges

The figures showed that the AA study group had the largest mean YBCGPI except between the ages of 40 and 54 years, which was due to a peak in tumour size in the AL study group. The EL study group had the smallest YBCGPI throughout most of the age range.

Table 3.25 compares YBCGPI in the three study groups. A significant difference was found between all the age groupings when AA was compared with EL, both when YBCGPI was taken as a continuous variable and as a prognostic category.

\* some cells with zero cases therefore  $\chi^2$  analysis not possible

When AA and AL YBCGPI (continuous variable) were compared there was no significant difference in either of the two younger age groups (pre menopausal and under 44 years) but there was a significant difference in the two older age groupings, although this was not seen in the over 44 year group when YBCGPI was considered as a prognostic category. There was no significant difference between AA and AL, by either assessment method when all ages were analysed.

In the comparison between AL and EL no significant difference was found, by either assessment method in either of the two older age groups. When YBCGPI was taken as a continuous variable a significant difference was found in both of the two younger groups. When all ages were considered there was a significant difference when YBCGPI was a continuous variable but not when prognostic categories were analysed.

Table 3.47 (page 167) gives a summary of the results of the clinic-biological section with reference to study group and age group.

| t Critical two-tail | 4.30                         |                             |

#### Table 3.26 Paired t-Test for two Samples Cellularity Vv

Comparison of the initial calculation and the repeat calculation for  $\nabla v$  shows that there is no significant difference (t<4.30). The result is supported by the high value of 0.98 for the Pearson correlation coefficient.

Table 3.27 Paired t-Test for two Samples VMI

| <b>An in the second s</b> | INITIAL CALCULATION<br>OF VMI | REPEAT CALCULATION<br>OF VMI |
|---|-------------------------------|------------------------------|
| Case one  | 21.29                         | 31.42                        |
| Case two  | 14.36                         | 15.26                        |
| Case three  | 11.16                         | 13.21                        |
| Pearson Correlation   | 0.98                          |                              |
| t Stat  | 1.50                          |                              |
| t Critical two-tail   | 4.30                          |                              |

There is no significant difference between the initial calculations of VMI and the repeat (t<4.30, Pearsons coef.=0.98).

# Cellularity

The volume fraction (Vv) assessed as part of the calculation of VMI is a measurement of cellularity.

| Study<br>group | Range     | Mean | Var  | SD   | Coeff Var |
|----------------|-----------|------|------|------|-----------|
| AA             | 3.7-9.49  | 7.77 | 1.15 | 1.07 | 13.79     |
| AL             | 3.55-9.36 | 6.94 | 1.47 | 2.16 | 21.2      |
| EL             | 3.78-9.12 | 6.82 | 1.74 | 1.32 | 19.32     |

Table 3.28 Comparison of Vv within the study populations

AA has the highest mean value of Vv and EL the lowest. AA shows the lowest coefficient of variation for Vv, values for AL and EL are very similar AL being slightly higher.

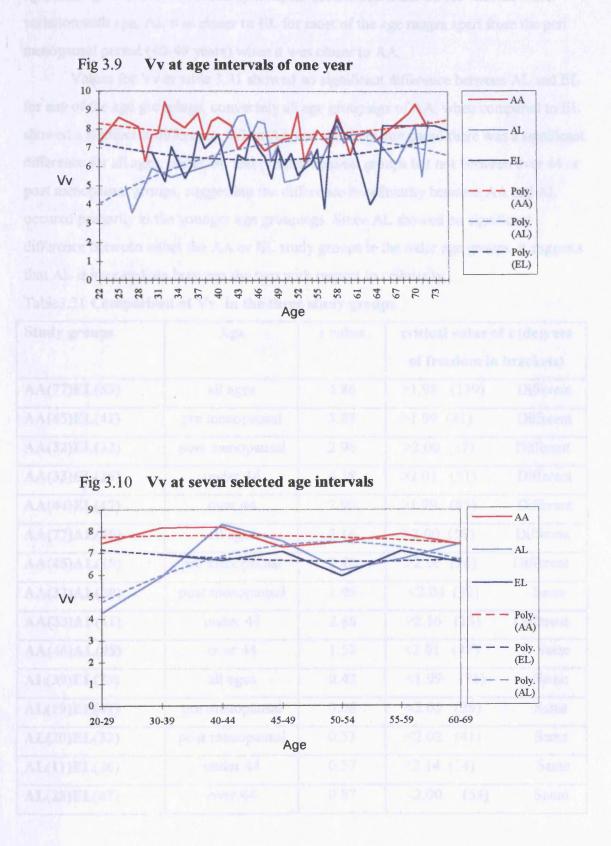

Table 3.29 Comparison of Vv within study groups

| Study<br>group | Age grouping                         | t value | critical value of t (degrees<br>of freedom in brackets) |
|----------------|--------------------------------------|---------|---|
| AA             | pre (45) and<br>post menopausal (32) | 0.53    | < 2.00(64)<br>Same                                      |
|                | under (33) and<br>over 44 years(44)  | 1.88    | <1.99 (69)<br>Same                                      |
| AL             | pre (19) and<br>post menopausal (20) | 0.03    | <2.03 (37)<br>Same                                      |
|                | under (11) and<br>over 44 years (28) | 1.10    | <2.12(16)<br>Same                                       |
| EL             | pre (41) and<br>post menopausal (32) | 0.56    | <2.00 (57)<br>Same                                      |
|                | under (26) and<br>over 44 years (47) | 0.08    | <2.00 (60)<br>Same                                      |

No significant difference was found in  $\nabla v$  within any of the three study groups for any of the age groupings considered in table 3.29. Data was compiled at age intervals of one year, and at seven selected age ranges (table 3.30), figs 3.9 and 3.10 were plotted from this data.

| Age   | AA   | AL   | EL   |
|-------|------|------|------|
| 20-29 | 7.44 | 4.24 |      |
| 30-39 | 8.16 | 5.92 | 6.93 |
| 40-44 | 8.18 | 8.32 | 6.66 |
| 45-49 | 7.26 | 7.54 | 7.06 |
| 50-54 | 7.50 | 6.19 | 5.95 |
| 55-59 |      | 6.72 | 7.09 |
| 60-69 | 7.40 | 7.42 | 6.57 |

Table3.30 Vv in seven selected age groups

Both figs 3.9 and 3.10 show AA and EL having similar trends with respect to age, although the level of cellularity is higher in AA. The trend for AL showed more variation with age, AL was closer to EL for most of the age ranges apart from the peri menopausal period (40-49 years) when it was closer to AA.

Values for Vv in table 3.31 showed no significant difference between AL and EL for any of the age groupings, conversely all age groupings of AA, when compared to EL showed a significant difference. When AA and AL were compared there was a significant difference for all ages, under 44, and premeno pausal groups but not between over 44 or post menopausal groups, suggesting the difference in cellularity between AA and AL occured primarily in the younger age groupings. Since AL showed no significant difference between either the AA or EL study groups in the older age groups, it suggests that AL is intermediate between the two with respect to cellularity.

| Study groups | Age             | t value | critical value of t (degrees |           |
|--------------|-----------------|---------|------------------------------|-----------|
|              |                 |         | of freedom in                | brackets) |

| AA          | 0.91-51.12                 | 13.31            | 83.72              | 9.15          | 68.76             |
| AL          | 1.22-56.59                 | 15.16            | 169.89             | 13.03         | 85.95             |
| EL          | 0.69-80.25<br>(0.69-53.15) | 13.82<br>(12.90) | 206.89<br>(146.78) | 14.38 (12.12) | 104.07<br>(93.93) |

Table 3.32 Comparison of VMI within the study populations

Numbers in brackets represent EL data after a single case with very high VMI (80)was removed.

AL had the highest VMI with both EL and AA having similar values. EL had the highest coefficient of variation and AA the lowest.

Table 3.33 Comparison of VMI within study groups

| Study<br>group | Age grouping<br>(number of cases in brackets) | calculated<br>t value | critical value of t<br>(degrees of freedom in<br>brackets) |           |  |
|----------------|---|-----------------------|--|-----------|--|
| AA             | pre(45) and post menopausal (32)              | 0.46                  | <2.00 (54)   | Same      |  |
|                | under (33) and over 44 years (44)             | 0.70                  | <1.99 (74)   | Same      |  |
| AL             | pre(19) and post menopausal (20)              | 0.42                  | <2.03 (37)   | Same      |  |
|                | under (11) and over 44 years (28)             | 0.04                  | <2.09 (19)   | Same      |  |
| EL             | pre(44) and post menopausal 29)               | 1.85                  | <2.00 (62)   | Same      |  |
|                | under (26) and over 44 years (47)             | 2.46                  | >2.01 (50)   | Different |  |

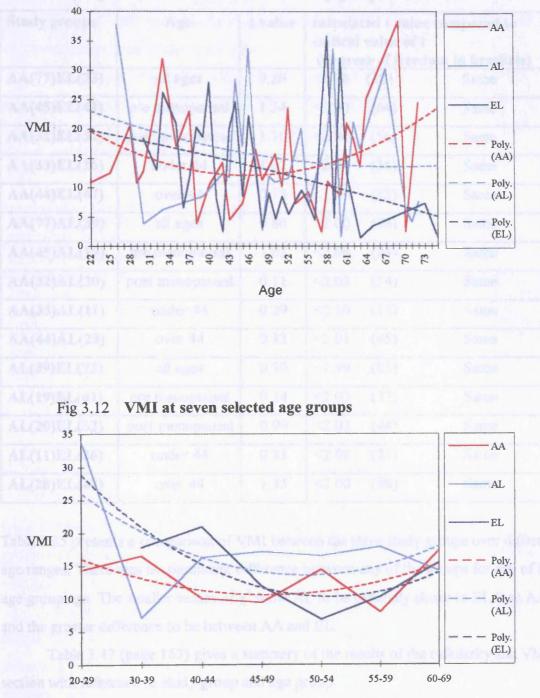

Table 3.33 only shows a significant difference in VMI between the under and over 44 old year age groups in EL, the difference however between the pre and post menopausal groupings in EL did not reach significance. When t was recalculated for EL under and over 44 years with out the high VMI case the new t value (3.2) was even larger, and therefore the difference more significant. AA and AL showed no significant difference between any of their age groupings.

Fig 3.11 shows VMI with respect to age, plotted at yearly intervals. The data was also grouped into seven selected age ranges, table3.34, and plotted in fig 3.12.

Table 3.34

VMI in seven selected age groups

| Age   | AA    | AL    | EL    |
|-------|-------|-------|-------|
| 20-29 | 14.33 | 33.96 |       |
| 30-39 | 16.49 | 7.09  | 17.81 |
| 40-44 | 10.03 | 16.25 | 20.96 |
| 45-49 | 9.42  | 17.14 | 11.90 |
| 50-54 | 14.38 | 16.51 | 6.82  |
| 55-59 | 7.92  | 17.85 | 10.27 |
| 60-69 | 17.30 | 14.18 | 15.48 |

Age

Figs 3.11 and 3.12 show much variation in all three study groups EL exhibited the most difference with age and AA the least. The high degree of variation may help explain the difference in the pattern of trend lines observed between figs 3.11 and 3.12.

| Study groups | Age             | t value | calcula             | ted t valu | e compared to    |
|--------------|-----------------|---------|---------------------|------------|------------------|
|              |                 |         | critical value of t |            | t                |
|              |                 |         | (degre              | es of free | dom in brackets) |
| AA(77)EL(73) | all ages        | 0.26    | <1.98               | (121)      | Same             |
| AA(45)EL(41) | pre menopausal  | 1.54    | <2.00               | (64)       | Same             |
| AA(32)EL(32) | post menopausal | 1.10    | <2.00               | (56)       | Same             |
| AA(33)EL(26) | under 44        | 1.62    | <2.02               | (38)       | Same             |
| AA(44)EL(47) | over 44         | 0.75    | <1.99               | (83)       | Same             |
| AA(77)AL(39) | all ages        | 0.80    | <2.00               | (58)       | Same             |
| AA(45)AL(19) | pre menopausal  | 1.02    | <2.06               | (24)       | Same             |
| AA(32)AL(20) | post menopausal | 0.11    | <2.03               | (34)       | Same             |
| AA(33)AL(11) | under 44        | 0.29    | <2.16               | (13)       | Same             |
| AA(44)AL(28) | over 44         | 0.83    | <2.01               | (45)       | Same             |
| AL(39)EL(73) | all ages        | 0.50    | <1.99               | (85)       | Same             |
| AL(19)EL(41) | pre menopausal  | 0.14    | <2.03               | (37)       | Same             |
| AL(20)EL(32) | post menopausal | 0.99    | <2.02               | (44)       | Same             |
| AL(11)EL(26) | under 44        | 0.83    | <2.08               | (21)       | Same             |
| AL(28)EL(47) | over 44         | 1.33    | <2.00               | (58)       | Same             |

Table3.35 Comparison of VMI in the three study groups

Table 3.35 presents a comparison of VMI between the three study groups over different age ranges. There was no significant difference between any of the groups for any of the age groupings. The smaller values of  $\chi^2$  show AL to be generally closer to EL than AA, and the greater difference to be between AA and EL.

Table 3.47 (page 167) gives a summary of the results of the cellularity and VMI section with reference to study group and age group.

## **3.5.6 NUCLEAR MORPHOMETRY**

### Specificity and reproducibility study

The results shown in table 3.36 demonstrate that the morphometric measurements of area were of sufficient sensitivity to be able to distinguish between two different cases selected at random and selected according to contrasting appearance, and also identify that there were no significant differences in nuclear area, within the same case, thus testing intra tumour variability.

The same set of microphotographs measured at different times were also not significantly different providing evidence for the reproducibility of the technique.

| Mean NA | VNA  | T test  | Comments   |

 Table 3.36 Specificity and Reproducibility T-Tests

#### Analysis of morphometric measurements at age interval of one year

Figures 3.13, 3.14, 3.15 for each of the study groups show sets of curves for the nuclear morphometric characteristics studied. All study groups showed marked variability for all the parameters. AL was slightly less variable at ages less than 42 but this may be attributed to low numbers of cases. Trend lines varied between the study groups AA appeared to vary least with age and EL the most showing a trend downwards with age.

Within each study group there was notable similarity between most of the curves, however shape and ratio of major and minor axis (D1:D2) appeared to be somewhat different in form. The morphometric measurements considered can be divided into two main categories, those which are primarily a function of size and others which are a function of shape. Parameters with size function are VNA, meanNA10, SDNA and SDNP (the latter is also influenced by the nuclear shape). The remaining two measurements, Shape and D1:D2, represent shape of the nucleus.

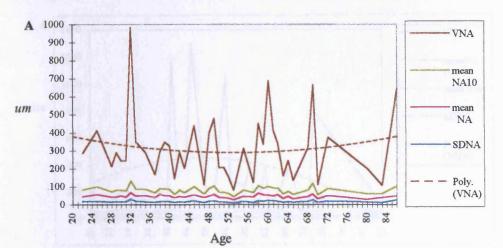

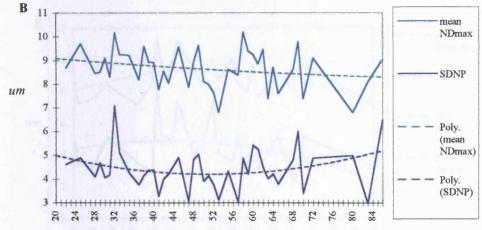

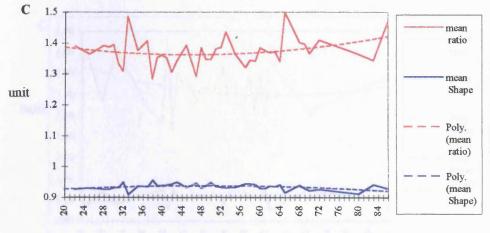

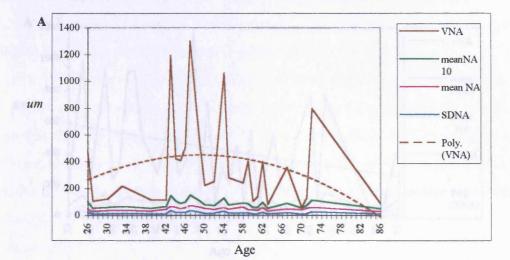

Fig 3.13 Nuclear morphometric measurements in AAat age intervals of one year

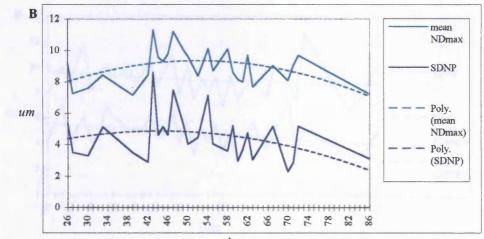

Age

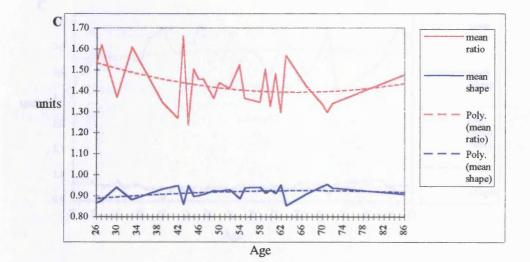

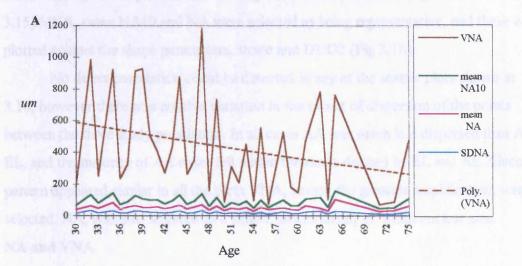

# Fig 3.14 Nuclear morphometric measurements in AL at age intervals of one year

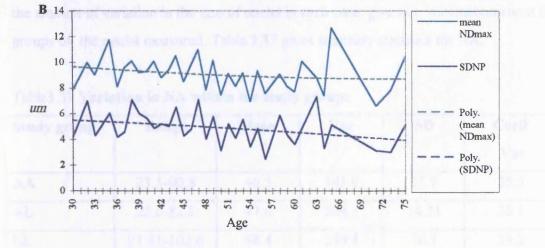

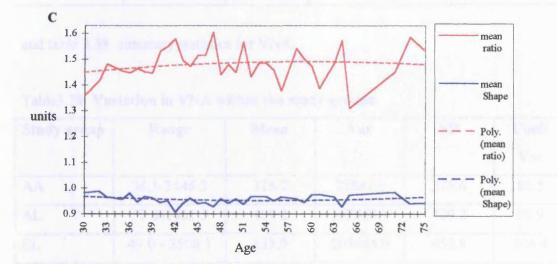

#### Comparison of nuclear shape with respect to size

To assess correlation between shape and size parameters, scatter plots were made. The three size parameters showing the most amplification (figs 3.13, 3.14, and 3.15) VNA, mean NA10 and NA were selected as being representative, and these were plotted against the shape parameters, shape and D1:D2 (Fig 3.16).

No direct correlation could be detected in any of the scatter plots shown in fig 3.16, however there was notable variation in the extent of dispersion of the points between the three study population. In all cases AA was much less dispersed than AL or EL, and the majority of AA cases fell within the range defined by EL and AL. Since the pattern appeared similar in all the plots VNA, having the greatest amplification, was selected. NA, was also selected as a simple measurement of mean nuclear size.

#### NA and VNA

Both NA, the mean nuclear area of the nuclei measured in each case, and VNA, the amount of variation in the size of nuclei in each case, give size information about the groups of the nuclei measured. Table 3.37 gives summary statistics for NA,

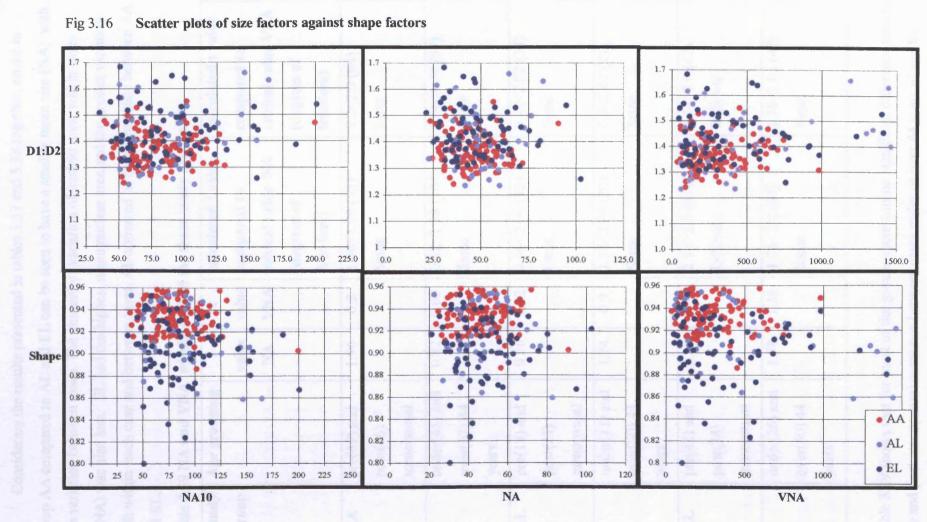

| Study group | Range       | Mean | Var   | SD    | Coeff |
|-------------|-------------|------|-------|-------|-------|
|             |             |      |       |       | Var   |
| AA          | 23.5-90.8   | 46.5 | 141.0 | 11.9  | 25.5  |
| AL          | 22.6-82.8   | 47.6 | 204.7 | 14.31 | 30.1  |
| EL          | 21.31-102.6 | 48.4 | 259.4 | 16.1  | 33.2  |

Table3.37 Variation in NA within the study groups

and table 3.38 summary statistics for VNA.

Table3.38 Variation in VNA within the study groups.

| Study group | Range         | Mean  | Var      | SD    | Coeff |
|-------------|---------------|-------|----------|-------|-------|
|             |               |       |          |       | Var   |
| AA          | 36.5-2445.3   | 318.2 | 75837.6  | 275.4 | 86.5  |
| AL          | 57.8-1461.5   | 409.2 | 167444.1 | 409.2 | 99.9  |
| EL          | 49.0 - 2508.1 | 433.7 | 205063.0 | 452.8 | 104.4 |

Considering the results presented in tables 3.37 and 3.38 together, nuclei in group AA compared to AL and EL can be seen to have a smaller mean size (NA) with less variation between cases. The amount of variation of nuclear area within cases (VNA) was also less. EL had the highest mean nuclear area and the greater variation both within each case and between cases. AL appeared to be intermediate between AA and EL.

| Study | Age grouping  | t     | t     | calculated t value | calculated t value |

|       | under(26) and | 1.78  | 1.38  | 1.78<2.0 (64)      | 1.38<2.01 (47)     |
|       | over(50) 44   |       |       | Same               | Same               |
|       | years         |       |       |                    |                    |

Table 3.39 NA and VNA within each of the three study groups

Table 3.39 shows that for most of the groups there was no significant difference between pre and post menopausal cases nor between cases under or over 44 years of age for either NA or VNA. Nuclear size therefore does not change significantly with age for these groups. The exception was the pre and post menopausal cases in study group EL where a significant difference was found in both NA and VNA. It is of interest to note that there was no significant difference when under and over 44 years cases for EL were compared. Values for under 44 cases and pre menopausal cases were very similar (meanVNA under 44=534.97 meanVNA pre menopausal=534.52) the difference being observed when older age groups were considered (meanVNA over 44=381.05, meanVNA post menopausal=309.16), similar pattern to that for NA. These observations indicate an apparent significant change in nuclear size between cases over and under the age of 50 years (menopause) in the EL cases studied.

| AGE   | NA AA | NA AL | NA EL | VNA AA | VNA AL | VNA EL |
|-------|-------|-------|-------|--------|--------|--------|
| 20-29 | 47.90 | 36.89 |       | 315.05 | 294.50 |        |
| 30-39 | 48.93 | 33.14 | 52.81 | 308.22 | 136.46 | 552.81 |
| 40-44 | 44.97 | 54.57 | 52.31 | 273.27 | 574.74 | 514.14 |
| 45-49 | 51.12 | 59.42 | 51.91 | 390.81 | 620.28 | 533.81 |
| 50-54 | 36.85 | 51.73 | 38.67 | 181.89 | 652.51 | 231.97 |
| 55-59 | 51.40 | 46.71 | 44.93 | 327.51 | 315.2  | 387.64 |
| 60-69 | 48.27 | 42.27 | 49.74 | 464.28 | 197.94 | 359.71 |

Table 3.40 Mean NA and VNA in seven selected age groups

Figs 3.17 and 3.18 prepared from the data in table 3.40 show the similarity of changes in NA and VNA with age in all the study groups.

NA in study group AA varied less with age than either AL or EL, and was the smallest for most of the age ranges. NA showed a greater difference between study groups pre menopausally, values for all groups converging to be closer by the age of 55 years; a similar pattern was seen for VNA.

AL was closer to AA under 40 years after which mean NA increased with values larger than those for EL, until at 55 years all groups tended to converge; and results for VNA were again similar. However small sample size in AL must be considered before generalising from these results.

#### Comparison of NA and VNA between the study groups in various age groupings

Table 3.41 shows that there was very little significant difference in NA between the study groups at any of the age ranges considered, only a comparison of AL and EL under 44 years showing a significant difference. Similarly there was very little difference in VNA, only AA and EL in the younger age groupings showing a significant difference.

#### Mean ratio of the maximum and minimum nuclear diameter and shape coefficient

Maximum and minimum nuclear diameter, D1:D2, and the shape coefficient  $(4\pi$  area/ (perimeter<sup>2</sup>)) shape, are both ratios which describe the shape of the nucleus, a perfect circle having a score of 1 for both D1:D2 and shape.

| Table 3.42 Variation in maximum and minimum nuclear diameter within the |
|---|
| study groups  |
|   |

|    | Range     | Mean | Var   | SD   | Coeff Var |
|----|-----------|------|-------|------|-----------|
| AA | 1.24-1.55 | 1.37 | <0.01 | 0.06 | 4.54      |
| AL | 1.24-1.66 | 1.42 | 0.01  | 0.11 | 7.99      |
| EL | 1.26-1.68 | 1.44 | 0.01  | 0.09 | 6.2       |

 Table 3.43 Variation in mean shape within the study groups

|    | Range     | Mean | Var   | SD   | Coeff Var |
|----|-----------|------|-------|------|-----------|
| AA | 0.89-0.96 | 0.93 | <0.01 | 0.01 | 1.54      |
| AL | 0.85-0.95 | 0.92 | <0.01 | 0.03 | 3.18      |
| EL | 0.8-0.95  | 0.9  | <0.01 | 0.03 | 3.27      |

None of the study groups showed much variation in either shape or D1:D2, AA having the lowest. AA was also closest to the value of one for both D1:D2 and shape and therefore had more regularly shaped nuclei. EL had the least regular nuclei and again AL had an intermediate value.

Table 3.44 presents the results of t-tests between different age groupings within the same study group. No significant intra group variation was found in any of the study groups for the two shape parameters, irrespective of age groupings.

| 50-54 | 1.38     | 1.47     | 1.42     | 0.94     | 0.91     | 0.91     |
| 55-59 | 1.35     | 1.41     | 1.43     | 0.94     | 0.93     | 0.90     |
| 60-69 | 1.39     | 1.40     | 1.40     | 0.93     | 0.91     | 0.91     |

Fig 3.19 and 3.20 were prepared from the data in table 3.45. Both figures show AA had the least amount of variation with respect to age. AA shows least shape deviation.

There was more difference between the study groups premenopausally, all three groups tended to converge during the post menopausal period. Throughout the age ranges AL was closer to EL than AA.

 Table 3.46 Comparison of D1:D2 and Shape in the three study groups

| Study<br>groups | age ranges<br>(years) | t<br>value<br>D1:D2 | t<br>value<br>Shape | calculated t value<br>compared to<br>critical value | calculated t<br>value compared<br>to critical value |

| EL(34)          | menopausal            |                     |                     | Same  | Same  |
| AL(11)          | under 44              | 0.02                | 0.54                | 0.02<2.16 (13)                                      | 0.54<2.12 (16)                                      |
| EL(26)          |                       |                     |                     | Same  | Same  |
| AL(30)          | over 44               | 1.12                | 2.52                | 1.12<2.00 (57)                                      | 2.52>2.00 (67)                                      |
| EL(50)          |                       |                     |                     | Same  | Different   |

Table 3.46 presents a comparison of D1:D2 and shape in the three study groups at different age groupings.

AA and EL varied the most, being significantly different for both shape parameters at all of the age groupings considered.

AL was also significantly different from AA for shape for all age groupings except the under 44 years of age. There was less difference between the two groups when D1:D2 was considered. Although there was a significant difference when all ages were compared, the difference was no longer significant when specific age groupings were compared.

When EL was compared with AL no significant difference was found for D1:D2 for any of the age groupings. When all ages were considered for shape however there was a significant difference, which appeared to be attributable to the over 44 years age group. Table 3.47 (page 167) gives a summary of the results of the morphometry section with reference to study group and age group.

#### 3.6 OVERALL SUMMARY

This summarises the points raised in sections 3.5.4, 3.5.5 and 3.5.6. Abbreviations used in figures and tables are as before except (c) indicates a continuous variable and (dc) a discontinuous variable.

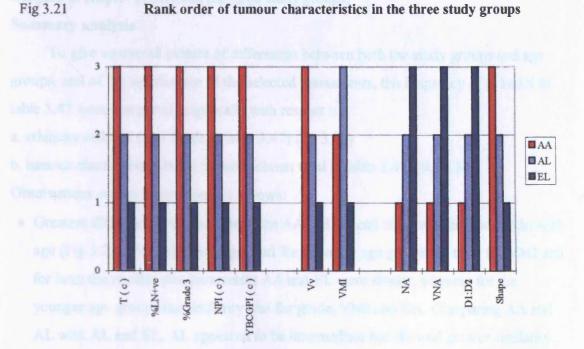

#### 3.6.1 INTRA GROUP VARIATION

- AA was the only one of the three study groups that showed no significant intra group variation for any of the parameters.
- AL was significantly different in the number of LN+ve cases when both pre and post menopausal groups, and under and over 44 years old groups were compared. The related measurement of YBCGPI was also found to be significantly different for AL.
- EL varied significantly for mitotic index, and both morphometric size parameters (NA and VNA).

#### 3.6.2 RANK ORDER

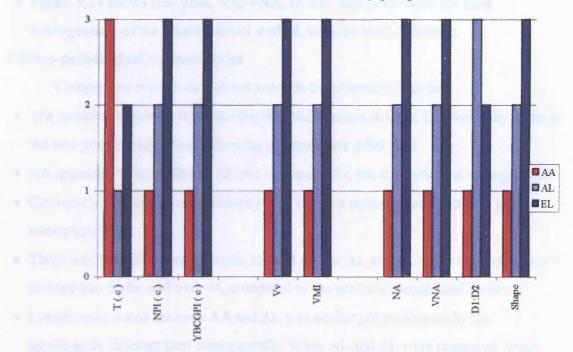

Each of the mean values for the tumour characteristics was given a rank order (1 for smallest- 3 for largest) and plotted for each of the study groups (fig 3.21) as was Coefficient of variation (fig 3.22). These two graphs demonstrate the following characteristics:

- AA has the largest mean tumour size, greatest percentage of lymph node positive cases, the highest percentage of grade three tumours, and correspondingly highest NPI and YBCGPI. AA also had the highest cellularity. EL had the lowest rank position for all these characteristics with AL being intermediate.
- AA however has the lowest morphometric size parameters and shape parameters closest to spherical. Conversely EL has the largest nuclear size parameters and shape parameters furthest from spherical.
- AA is the most homogeneous of the study groups having the lowest coefficient of variation for all the tumour characteristics assessed, with the exception of tumour size. AA showed the greatest variation in tumour size.
- For all characteristics, except T (c) and D1:D2, EL was the most heterogeneous of the three study groups.

NB. Graph was plotted after the exclusion of a single high VMI value in the EL study group. If included the rank order would read AL,EL,AA not AL,AA,EL

Fig 3.22 Rank order of coefficient of variation in the tumour characteristics for the three study groups

#### **3.6.3 INTER GROUP COMPARISON OF TUMOUR CHARACTERISTICS**

Table 3.47 is a summary of the comparison of all the tumour characteristics analysed in chapter 3, between the three study groups.

#### Summary analysis

To give an overall picture of differences between both the study groups and age groups, and of the significance of the selected parameters, the frequency of D and S in table 3.47 were compared graphically with respect to:

a. ethnicity and age (row totals in table 3.47) (fig 3.23)

b. tumour characteristic being tested (column total in table 3.47) (fig 3.24)

Observations can be summarised as follows:

- Greatest difference was found between AA and EL and there was little variation with age (Fig 3.23). For combined ages and for the older age groupings tests for VMI and for both the nuclear size parameters AA and EL were similar, whereas for the younger age groups the similarity was for grade, VMI and NA. Comparing AA and AL with AL and EL, AL appeared to be intermediate but showed greater similarity to EL. When age groupings for AA and AL were examined there was greater similarity pre menopausally compared to post menopausally, and also greater similarity under 44 compared to over 44 years of age. However when age groupings for AL and EL were compared the similarity was greater in the older age groupings.
- Figure 3.24 shows that VMI, NA, VNA, D1:D2 and grade were the most homogeneous of the characteristics studied, with the least difference.

#### **Clinico-pathological characteristics**

Comparison reflects the pattern noted in the summary analysis:

- The greatest difference was between the study groups AA and EL, with only grade in the two younger age groups showing no significant difference.
- AA appeared to be similar to AL pre menopausally, but different post menopausally.
- Conversely AL had greater similarity with EL post menopausally and least pre menopausally.
- There was less difference between AA and AL, or AL and EL when the groups were divided into under and over 44, compared to the pre/post menopausal division.
- Lymph node status between AA and AL was similar pre menopausally but significantly different post menopausally. When AL and EL were compared lymph node status for both pre menopausal and under 44 years cases were significantly different, but not post menopausally or over 44 years.

# Table3.47 Summary of tumour characteristics (Key to symbols in text)

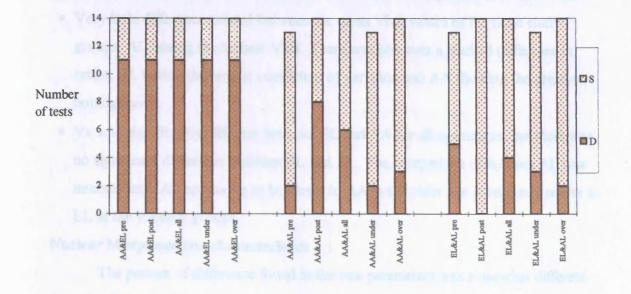

Fig 3.23 Comparison of degree of difference between study groups

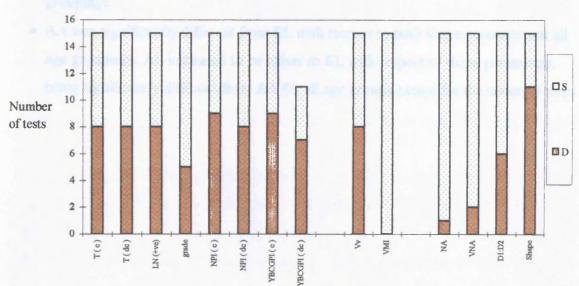

Fig 3.24 Comparison of degree of difference between tumour characteristics

KEY

Number of tests showing significant difference (D)

Number of tests showing no significant difference (S)

#### **Cellularity and VMI**

These do not follow the pattern observed for clinico-pathological characteristics:

- The range of cellularity was similar for all three study groups, but AA, having a lower coefficient of variation, appeared to be more homogeneous than AL or EL.
- Very little difference existed between the mean VMI values of the three study groups, AL having the highest VMI. There was however a marked difference in range, EL having the largest coefficient of variation and AA showing the greatest homogeneity.
- Vv was significantly different between EL and AA for all age ranges, but there was no significant difference between EL and AL. The comparison of AA and AL was intermediate, AL appearing to be closer to AA in the older age groups and nearer to EL in the younger groups.

#### **Nuclear Morphometric characteristics**

The pattern of difference found in the size parameters was somewhat different from that between shape parameters:

- There was little significant difference in size parameters, and it is notable that the three tests in which a significant difference were detected are all in younger age groupings.
- AA was significantly different from EL with respect to both shape parameters at all age groupings. AL appeared to be closer to EL with respect to shape parameters, being significantly different from AA for all age groups except for the under 44 years.

## **3.7 DISCUSSION**

#### **3.7.1 SELECTION OF CASES**

The aim of this chapter was to analyse and compare surrogate markers of breast cancer occurring in the three study groups, taking into consideration their ethnic origin and age of patients.

The first step was to obtain material for study from breast cancer cases occurring within the Western Region. Since it was not possible to discriminate between Saudis and non-Saudis from the information available it was necessary to establish that there were no significant differences between the two breast cancer populations with respect to age. The majority of non-Saudis in the Western Region are contract workers. The population therefore comprises mainly individuals between the ages of 20 to 65 years of age, and fewer older or younger individuals would be expected. The ages of Saudi and non Saudi patients in the registry from the crude frequency data was examined up to the age of 65 years (retirement age). Less cases would be expected in the older age group since the majority of contract workers or spouses of workers return home at retirement age. The t-test performed on the data from the Saudi and non-Saudi breast cancer populations shows that there is a greater than 95% probability of them belonging to the same population. The results of the Z test also shows that there is no significant difference in the mean age of onset of the two data sets and they can be considered as coming from the same population. In view of this and that the non-Saudi population are of similar ethnic make up to the Saudi population, all non-Saudis from low incidence countries in the study group of the Western Region were included in the study group for the Western Region.

Ideally the study population should be selected at random from within the NCR data base for the Western Region; the referral hospital and patient medical record number recorded, and the required samples and patient and tumour information obtained from the referral hospital. However the cases available for study were limited, both by access to the data and material and the quality of the samples. Permission for access to data and samples had to be obtained on a hospital to hospital basis; ethical committee clearance, permission from the senior administration and the individual laboratories had to be obtained, and this was not always possible. In addition to these limitations the quality of the samples varied, some not having the quality of fixation required for morphometry. Others had insufficient material remaining (this was particularly true in hospitals having an active research program). Within these limitations data was collected from five major hospitals in Jeddah, samples being available from three of them. All

available cases of invasive carcinomas were examined and material collected so within each hospital there was no selection bias. In addition the five hospitals are located in different areas of Jeddah, serving a wide range of socio-economic groups. The raw data from these hospitals was compared with the raw data from the NCR Western Region and it was concluded that the Jeddah data base can be considered as a statistically representative sub group of the NCR Western Region data base, with respect to age. To ensure a suitable standard quality, all samples were examined by Dr Rosemary Walker (who was also responsible for selecting the breast cases from Leicestershire), before inclusion in the study. From hospitals where many blocks were found to have limited material due to past research, only data was collected since it was felt that use only of blocks not previously utilised would introduce possible bias.

The majority of cases for which sections were available were from the period 1991 to 1997. In order to be comparable Leicester European cases were selected from between 1993 and 1995 and were age matched. They were not consecutive cases since they came from a research bank collected by Dr Walker. These were cases for which tissue had been frozen and a block for fixation and processing taken, which was separate from the routine diagnostic material. This meant that the tumours had to be of a sufficient size to allow this, therefore precluding tumours 10-15mm in maximum diameter. Cases which had received therapy prior to surgery and screen-detected cases were excluded.

The number of cases of breast cancers occurring in Leicester Asians was limited and so the computer files of Leicestershire Pathology Service were searched for invasive carcinomas in that population for the period 1982 (start of computerisation) to 1998. Again pre-operative chemotherapy/ radiotherapy and mammographic detection were exclusion criteria.

#### **3.7.2 METHODOLOGY**

Once the cases for the study groups had been identified, care was taken at all stages to, as far as possible, avoid selection bias and yet at the same time avoid the introduction of additional variables which might act as confounding factors. One of the biggest variables affecting nuclear morphometry and mitotic index is fixation of tissues. The majority of cases from Leicester were optimally fixed prior to processing (see methods). Because the Leicester Asian cases were from a wider time frame the fixation schedule was more variable, but blocks were selected that gave the best preservation. The situation in Jeddah is more complex because several different institutions were involved. Within these institutions different companies are employed to operate the

hospitals with the Saudi staff, and these companies come from various parts of Europe and North America often bringing with them their own standard protocols.

All of the cases from Jeddah were reviewed by Dr Walker and only blocks with good preservation with regards to fixation and processing were selected. There were five cases where only tissue that had been used for frozen section analysis was available but in which the nuclear features were still sufficiently well preserved. Freezing and thawing of tissues can lead to nuclear collapse (Baak and Ort, 1991; Kronqvist et al, 1995), and such sections were only used when there was no evidence of nuclear collapse and when no other material was available.

Another important variable is section thickness. All sections from Leicester were cut on the same microtome by one person (Mrs S.J.Dearing). The Jeddah cases were from three different laboratories each with a different microtome and a different person cutting. However greater variations were seen in the EL group than the AA group suggesting that these technical differences did not contribute.

The stringent guidelines suggested by Baak et al (1982) were followed for both the nuclear morphometry and the mitotic index measurement, and preliminary experiments confirmed the reproducibility of the measurements and their sensitivity to distinguish between measurements from within the same tumour and between two tumours selected at random. Baak et al (1982) found 25-50 nuclei sufficient for reproducible assessments but others have used more, e.g. Pienta and Coffey (1991) used 150 nuclei. In this project between 100-150 nuclei were measured since once measurement was started on a microphotograph image then all tumour nuclei on that image were measured, to avoid selection bias (see Methods). Cases were identified by slide number until after measurements were completed when the code indicating age and ethnic origin was allocated. Because of labelling it was possible to distinguish Leicester slides from Jeddah slides, but the ageof the patient or whether they were AL or EL was not known until after the measurements were completed.

#### **3.7.3 ANALYSIS**

The age groupings for statistical analysis were formulated so that the prognostic indicators could be compared in pre and post menopausal patients. In chapter 2 I demonstrated that there were differences in the relative risk of breast cancer between the populations of the Western Region, and the Leicester Asian and European populations when cases were grouped above or below the age of 44 years, so these age groupings were also investigated.

For the continuous variables (absolute tumour size, NPI, YBCGPI, Vv, mitotic index, and the selected morphometric measurements), the data was divided into seven selected age groups, 5 year intervals over the age range 40 - 59 years, 10 year intervals at 20-40 years and 60-69 years. It was not possible to use 5 year intervals through out because of insufficient cases at the two extremes. A graph at yearly age intervals was plotted, to illustrate the amount and distribution of heterogeneity with respect to age, and to demonstrate if trends found in summarised data could be applied in the individual data. Both of these graphs had polynomic trend lines inserted to aid comparison.

The coefficient of variation, the standard deviation expressed as a percentage of the mean, was used because it allows comparison of the variation within a data set independent of scale and unit (Daniel, 1991). Using this approach it was possible to demonstrate the amount of variation and thus the extent of heterogeneity in the continuous variables within each study group.

T-tests were performed between pre and post menopausal, and under and over 44 year old within each study group to assess if there were significant differences within the groups with respect to age. To compare differences between groups t-tests were performed between AA and EL, AA and AL, and AL and EL, for all ages, pre and post menopausal, and under and over 44 years of age. By using different age splits it was possible to assess not only if significant differences existed but also to help identify the age range with the greatest difference.

For the non continuous variables (tumour size under or over 2cm, node status, grade, NPI and YBCGPI categories),  $\chi^2$  analysis was performed to compare values between pre and post menopausal, and under and over 44 year old within each study group. This was to assess if there were significant differences within the groups with respect to age, and to compare differences between groups using the same age splits as for the continuous data.

#### 3.7.4 FINDINGS

In chapter 2 I demonstrated that there are differences in the incidence of breast cancer for the age range 20-69 years between the Western Region, Leicester European and Leicester Asian populations. Significant differences were identified for the under and over 44 year old group between the Leicester Europeans and the Western Region, whilst the Leicester Asian population in the 20-44 age range were similar to the Western Region, and the 45 and over range closer to the Leicester Europeans. In this chapter I have examined a range of biological features to determine whether there are other differences present apart from incidence.

Comparison of the basic statistics of each surrogate marker for each study group results in the following general profile of tumours (figs 3.21, 3.22).

#### Ethnicity

When clinico-pathological parameters are considered AA appears to have a worse prognostic profile than EL (fig 3.21), and with the exception of the younger age groupings, for grade these differences are statistically significant (table 3.47). Similar findings of large tumour size (Krieger et al, 1997; Ijaduola and Smith, 1998), and high percentage of lymph node involvement (Aziz et al, 1999; Boyer-Chammard et al, 1999) and high grade tumours (Mohla et al, 1982), have been reported for patients in other low breast cancer incidence populations.

Most tumour morphometry studies have examined the relative prognostic value of the morphometric parameters (Theissig et al, 1996; Kronqvist et al, 1998) rather than differences attributable to age or ethnic origin. In general these studies found larger NA, higher degree of pleomorphism, and higher VMI to be poor prognostic factors. With the exception of Vv and VMI, EL has a worse prognostic profile than AA for the morphometric parameters.

Baak et al (1992) studying two populations in different areas of Denmark found that although age, lymph node status, and tumour size were similar, morphometric parameters and 10 year survival rate varied; the population with the worse morphometric profile having the poorer survival rate. Although the two populations in Baak's study were fairly close, the morphometric profile appeared to be independent of the clinicopathological profile and could have a significant input on prognosis.

Several studies report patients from low incidence populations as having poorer survival (Vernon et al, 1985; Wojcik et al, 1998). Although follow up data was not available for the cases studied, the poor prognostic profile of AA is reflected in the values for NPI and YBCGPI which are significantly worse than those for EL. Despite the poor prognostic profile from clinico-pathological parameters results from follow up studies on Saudi breast cancer cases suggest that survival and disease free interval (dfi) are not significantly different from those found in the West (Ibrahim et al, 1998; Vijay and Raadi pers com). A comparison of British and Japanese patients (Merchant et al, 1999) found premenopausal Japanese patients to have larger tumours than their British counterparts and yet, despite both groups having similar profiles for c-erbB2 and p53 expression, a better dfi and overall survival. Differences in nuclear morphometric characteristics, such as those described in the AA population, could balance out the

clinico-pathological parameters and so provide a possible explanation for these apparently contradictory results.

#### Age differences

Comparison of grade between AA and EL shows it to be influenced by age (table 3.47). Although the overall occurrence of grade 3 tumours was significantly greater in AA, there was no significant difference between AA and AL, or AL and EL for the younger age groups (pre menopausal, and under 44). Table 3.14 shows that the younger groups generally have a higher percentage of grade three tumours than the older groups, although none of these reached statistical significance. These findings are in agreement with earlier studies that have found a higher proportion of grade three tumours in younger patients (Walker et al, 1996; Gillette et al, 1997; Fisher et al, 1997). There is a slightly higher percentage of grade 3 in AA post than AA pre but both are high; this probably reflects the degree of homogeneity in the AA tumour population discussed previously.

Edwards et al (1998) found the ratio of LN+ : LN- decreased with age for AmW but remains relatively constant for AmB, the low incidence population. However the results presented here are somewhat different. In the AL study group LN status was found to vary significantly with age in a similar manner to AmW in Edwards et al study. However in the other groups there was no significant difference with age although there was generally proportionally more LN+ve cases in the younger than in the older groups. Differences may reflect the intrinsic heterogeneity of breast cancer or be artifactual due to the small numbers in some of the age sub groupings, especially AL.

Three parameters showed no significant difference when combined age groups, "all ages", were compared for AA and EL: VMI, NA, and VNA. However VNA showed significant differences when both of the younger age groupings (under 44 and pre menopausal) for AA and EL were analysed. Tests for VNA between AA and AL, and between AL and EL all show no significant difference for any of the age groupings. This suggests that there may be ethnic differences in VNA in young breast cancer.

Comparing AA and EL, VMI and NA showed no significant differences regardless of age group. This suggests that within the populations studied these factors are generally independent of age and ethnic origin. An exception is the finding of a significant difference between AL and EL for NA in the under 44 age group, which, assuming that it not an artefact due to the small size of the AL group, might reflect age related differences between AL and EL.

#### **3.7.5 Conclusions**

Grade and lymph node status, in particular, appear to vary with age, although AA shows greater homogeneity with age for the parameters studied compared to EL. An interesting observation from figs 3.21 and 3.22 is that AA appears to have a poor prognostic profile compared to EL if clinico-biological parameters are considered, but morphometrically appears to be better than EL. EL conversely shows the worst, but more variable morphometric profile but has a better clinico-biological prognostic profile than AA. Furthermore table 3.47 shows most of these differences to be statistically significant.

The observed differences in the parameters studied may therefore reflect underlying different genetic alterations, and these could vary between ethnic/age groups.

# CHAPTER FOUR

# COMPARISON OF SELECTED GENETIC ALTERATIONS WITH REFERENCE TO AGE AND ETHINICITY IN THE THREE STUDY POPULATIONS

## **4.1 INTRODUCTION**

The three study populations have been shown to vary in terms of the pattern of incidence of breast cancer (2.6), and prognostic indicators (3.6), which raises the possibility that breast cancer arising in the three populations may vary genetically with respect to age and/or ethnic origin. The general trend of the results appears to show age specific ethnic differences, with the Leicester Asian (AL) group tending to be intermediate between the Saudi (AA) group and the Leicester European (EL)group. Similarities between AA and AL breast cancers are more pronounced pre menopausally with AL breast cancers tending to have a closer relationship with those in the EL population in the older age range. The menopause, and the pre menopausal period appears to be a pivotal point in the relative nature of breast cancer in the three study groups. Also, from the study of the prognostic indicators, both Asian study groups appear to be more homogeneous than the European group, in addition to having larger tumours of a higher grade and more lymph node involvement at an earlier age than the European group.

It was therefore decided to compare cancers from the three study groups genetically, using determination of loss of heterozygosity / allelic imbalance as the investigatory tool.

#### 4.1.1 ALLELIC IMBALENCE AND LOSS OF HETEROZYGOSITY

Loss of heterozygosity (LOH) of an allele in a tumour when compared to the patients constitutive DNA may not always present as complete loss but as a change in the relative strength of signal, when most copies of one allele have been lost or if copies of the second allele have been gained. Although this situation, where gels only show a partial loss of a band, has improved due to techniques such as microdissection it may be present due to intra tumour heterogeneity.

Gain of an allele is not recorded as frequently in the literature for solid tumours. Devilee et al (1991) reported allelic gain in a breast tumour associated with 1q, in the same paper Devilee introduced the term allelic imbalance, AI, it being more comprehensive and inclusive of cases of LOH. Trisomy, which has been recorded in several chromosomes in breast cancer (Gebhart et al, 1986; Cavalli et al, 1997; Adeyinka et al, 1997), would result in a gain in intensity of one allelic band. Localised amplification, as occurs in homogeneously staining regions which have been recorded in breast cancer (Dutrillaux et al, 1990; Muleris et al, 1995; Bernardino et al, 1998), would also have the same effect.

#### **4.1.2 LOSS OF HETEROZYGOSITY IN BREAST CANCER**

#### Sites identified as exhibiting LOH in breast cancer

There have been many studies analysing LOH in breast cancers, and specific sites of AI have been identified on many chromosomes, reviewed by Devilee and Cornelisse (1994).

 Table 4.1 Allelic Imbalance in Breast Cancer

| Chromosome | % informative cases showing | Range (%) of AI at different |
|------------|-----------------------------|------------------------------|
| arm        | AI                          | sites along the arm          |
| lp         | 26.5                        | 3 - 47                       |
| 1q         | 33.0                        | 0 - 50                       |
| 3p         | 33.6                        | 9 - 47                       |
| 6q         | 36.4                        | 9 - 52                       |
| 7q         | 23.7                        | 0 - 41                       |
| 8p         | 38.7                        | 27 - 50                      |
| 9q         | 24.0                        | 9 - 36                       |
| 11p        | 27.1                        | 8 - 41                       |
| 11q        | 53.0                        | 42 - 66                      |
| 13q        | 27.7                        | 0 - 33                       |
| 16q        | 52.3                        | 40 - 62                      |
| 17p        | 57.0                        | 37 - 75                      |
| 17q        | 38.6                        | 5 - 75                       |
| 18q        | 20                          | 3 - 36                       |

Most of the chromosomes exhibit more than one possible site of AI, the frequency varying between sites. Changes in 6q, 7p, 16q, 17p, and 17q appear to be early events in the process of tumourigenesis, since they have been detected in between 25 - 50% of in situ ductal carcinoma (Stratton et al, 1995; Walker et al, 1997). A recent study, Buerger et al (1999b), using comparative genomic hybridisation (CGH), a technique which allows the entire genome to be screened for loss or amplification of loci, have reported frequent occurrence of AI at additional loci including losses at 11q and gains at 1q.

CGH has also been used to compare lymph node positive and lymph node negative tumours. Studying lymph node negative tumours Hermsen et al (1998) found gains in 8q, 1q, Xq, 5q,4q,and 3q, and losses at 19p, 1p, 17p, 22q, 4q and 8p, whereas Adeyinka et al

(1999) reports a higher frequency of losses in l6q, 6q, and chromosome 10, and gains at chromosome 18. A possible explanation for the apparent disparity between these studies may be due to intra tumoural heterogeneity, Aubele et al (1999) demonstrated such heterogeneity; using micro dissection and CGH. Even normal tissue associated with a tumour may show genetic heterogeneity; including LOH (Lakhani et al, 1999).

#### Significance of LOH in tumour progression

McGuire and Naylor (1989) discussed the question as to whether LOH in cancer was cause or effect of tumour progression. Vogelstein et al (1989) proposed two explanations for the observed LOH in tumour cells; either that it is caused by a deletion closely linked to a tumour suppressor, and so has a role in neoplastic progression, or that the observed AI, including LOH, are random events being the consequence of neoplastic progression. Chen et al (1992) investigated this problem by examining 98 cases of breast cancer for LOH in 12 different chromosomal regions. Five of these regions were randomly selected from areas not known to be prone to LOH, to act as a baseline against which to assess non specific LOH. Seven regions were selected at known sites of LOH in breast and other cancers. The randomly selected areas resulted in a baseline level of LOH at 4% (5/124 tests) whereas 6 of the 7 LOH associated sites had LOH in excess of 21%. From these experiments Chen et al (1992) concluded that LOH in breast cancer is not a random event. **Association of loss of heterozygosity with clinico-pathological parameters** 

#### Tumour Size

Studies have found a correlation between total LOH and tumour size; Nagayama and Watatani (1993) comparing tumours under and over 2cm, and Kerangueven et al (1997) in a study of 75 tumours tested with 185 microsatellite markers.

#### Lymph node involvement

Diverse results have been found comparing LOH with LN status. LOH at 16q and p53 have both been associated with LN+ tumours (Sato et al, 1990; Takita et al, 1992), although other studies on 16q have found no association at all (Cleton-Jansen et al, 1994) or an association with LN-ve tumours (Caligo et al, 1998).

#### Grade

A high total incidence of LOH in a tumour is associated with a high grade and a poor prognosis (Iwase et al,1998). Although LOH at some loci has been associated with low grade, in particular 16q (Hansen et al, 1998; Roylance et al, 1999) others have failed to find

this correlation (Tsuda et al, 1994; Tsuda et al, 1999) (see section 4.1.3).

#### Somatic Mutations and Loss of Heterozygosity

Loss of heterozygosity at a site on a chromosome is taken as being indicative of the possible proximity of a tumour suppressor gene (Lasko et al, 1991). LOH studies utilising microsatellites have been frequently used to locate potential tumour suppressor genes (Sato et al, 1990; Tsuda et al, 1994; Orphanos et al, 1995). According to Knudsens two hit hypothesis the remaining allele should have a mutation and the protein product of the gene either absent or non functional (section 1.3.2 fig 1.7). However there are many other cases where no such correlation can be found and where the remaining allele appears to be wild type with no mutations (Thompson et al, 1992; Deng et al, 1994). However mutations may be more frequent in tumours which exhibit LOH (Mazars et al, 1992).

Assuming that the LOH is greater than 4% and therefore non random there are several alternative scenarios which could account for this apparent paradox:

1.Loss of one copy of the tumour suppressor without a mutation in the second, could result in a growth advantage due to dosage effect (Deng et al, 1994).

2. The undeleted allele may be silenced by aberrant methylation of the gene promoter region or of a controlling gene (Ottaviano et al, 1994; Petrangeli et al, 1995; Bilanges et al, 1999).
3. LOH may occur at several sites in the same tumour and combined hemizygosity at two or more specific loci may contribute to the process of tumourigenesis (Di Cristofano et al, 1998).

4. Aberrant post transcriptional or post translational modification of the product of the undeleted allele.

5. The LOH may be affecting an alternative tumour suppressor, rather than the candidate gene (Kashiwaba et al, 1995).

#### 4.1.3 SELECTION OF CHROMOSOMAL REGIONS FOR STUDY

Three chromosomal regions were chosen which had previously been investigated in breast cancer and been shown to have high incidence of AI (Devilee et al, 1991). The aim was to determine whether there is any difference in the incidence of allelic imbalance within cancers from the three study groups.

#### Chromosome Arm 6q

#### Possible relevance to breast cancer

Deletion involving chromosome arm 6q is the second (Devilee et al, 1991) most frequently recorded changes in breast tumours (Dutrillaux et al, 1990; Mars and Saunders, 1990; Takita et al, 1992). Studies of microsatellite polymorphisms confirm the deletion on 6q seen in the cytogenetic studies (Mars and Saunders, 1990).

AI has been described at 6q13 (Devilee et al, 1991; Orphanos et al, 1995), 6q21 (Noviello et al, 1996) and 6q23.3-25 (Theile et al, 1996). Sheng et al (1996) identified at least three regions 6q14-q16.2, 6q16.3-q23, and 6q22.3-23.1. AI has also been observed at 6q24 - 27 (Orphanos et al, 1995) and deletions in the region 6q24-25 have been correlated with advanced tumours and an aggressive phenotype (Noviello et al, 1996). Noviello et al (1996) found four regions of LOH 6q13, 6q27, 6q21, 6q24-25. Iwase et al (1995) correlated total LOH on 6q with increased grade and age, patients over the age of 50 years having a significantly higher incidence of LOH.

These studies indicate the presence of at least three or four potential tumour suppressor genes on chromosome arm 6q. Region 6q24-27 is of particular interest because it includes the ER locus.

#### Candidate tumour suppressors in the region 6q24-27

The oestrogen receptor gene is located on the long arm of chromosome 6 at 6q25.1 (Orphanos et al, 1994). The function of the ER is as a transcription factor and it is activated by oestrogen. With the pivotal role oestrogen has in breast development, menarche and menopause, the oestrogen receptor gene is an obvious candidate when considering a condition of the breast with possible different pre- and post- menopausal manifestations. Oestrogen receptor expression is lost in 30-40% of sporadic breast tumours (Clark and McGuire, 1988) and these oestrogen receptor negative (ER-ve) tumours tend to be poorly differentiated and have a poorer prognosis than receptor positive tumours. However deletions within the ER gene region do not appear to correlate with the loss of the oestrogen receptor, since several studies have found the oestrogen receptor to be present even in the presence of these deletions (Iwase et al, 1995; Noviello et al, 1996; Chappell et al, 1997). LOH was found in 19% of informative tumours (Iwase et al, 1995).

Another gene within this region has also been proposed as a tumour suppressor; Bilanges et al (1999) described a gene ZAC located at 6q24-25, close to the ER gene which shows loss of expression in primary breast cancer, although none of the 45 tumours selected for LOH in this region had any detectable mutation in the remaining allele. The ZAC gene is thought to be involved in the induction of apoptosis and control of the cell cycle (Bilanges et al, 1999).

#### Chromosome Arm 16q

#### Possible relevance to breast cancer

AI has frequently been reported in the long arm of chromosome 16 (Sato et al, 1990; Takita et al, 1992; Tsuda et al, 1994). Comparative genomic analysis has also confirmed these losses (Schwendel et al, 1997). Locus 16q24.2 has the highest incidence of AI (Cleton-Jansen et al, 1994) in breast tumours independant of stage (I-III) (Tsuda et al, 1994) suggesting that it is an early event in tumourigenesis. However LOH at 16q24 has also been correlated to the occurrence of distant metasises (stage IV) (Lindblom et al, 1993). Sato et al (1990) found a correlation between LOH at 16q24 and lymph node metastases, however this correlation failed to reach statistical significance and in a later larger study by the same group (Takita et al, 1992) could not be demonstrated. Conversely Caligo et al (1998) found LOH at 16q correlated to lymph node negative tumours. Cleton-Jansen et al (1994) found no correlation with lymph node status, histology, stage or grade, but did find a correlation between LOH at 16q with ER positive tumours. LOH at 16q was however associated with low grade and to be a marker of good prognosis independent of menopausal status (Hansen et al, 1998). Fujii et al also quotes LOH at 16q as being independent of age.

At least two other regions along this arm appear to be hot spots for AI, 16q22.1 (Cleton-Jansen et al, 1994; Dorion-Bonnet et al, 1995), and 16q22-23 (Sato et al, 1991). Known genes of interest in the region 16q24

There have been several candidate tumour suppressor genes proposed within this region. Chromosome arm 16q is the site of seven of the cadherin family of genes (Kremmidiotis et al, 1998) some of which are expressed in breast tissue (1.1.3).

H-Cadherin is located at 16q24 and is also a potential tumour suppressor (Kremmidiotis et al, 1998). It is occasionally found to be mutated in breast carcinomas (Miki et al, 1997) and has diminished expression in breast cancer (Lee, 1996), whereas expression of the wild type gene inhibits tumour formation (Lee et al, 1998).

A second region of LOH at 16q 22.1 is also the location of a cadherin genes, Ecadherin and P-cadherin (Kremmidiotis et al, 1998). In microcell hybrid experiments a gene SEN16 located at 16q24.3, just proximal to D16S413, was found to restore cellular senescence to selected immortalised breast cell lines, making it a candidate tumour suppressor (Reddy et al, 1999). Gene 16S4448, BBC-1 (Breast basic conserved gene), also located at 16q24.3, was found to be expressed at higher levels in benign fibroadenomas compared to breast carcinoma, however a function for the gene is unknown (Cleton-Jansen et al, 1995). Another gene located at 16q24.3 is the CAR/CARM (Cell adhesion regulator molecule) described by Pullman and Bodmer et al (1992). A later study (Moerland et al, 1997) excluded the role of tumour suppressor gene for the BBC-1 gene and the CAR/CARM gene. However this decision was done on the basis of observations that no mutations were found in the remaining allele after LOH.

#### **Chromosome Arm 17p**

#### Possible relevance to breast cancer

Early studies using restriction fragment length polymorphism analysis generally found AI at 17p in 32% of cases using the BHP3 probe, and in 47 % with the YNZ22 probe (Sato et al, 1990). The BHP3 probe is closely related to the P53 locus at 17p12 whereas the YNZ22 probe maps to a more distal region at the tip of 17p (Takita et al, 1992), indicating at least two possible tumour suppressor genes on 17p. Microsatellite studies also confirm these results (Kirchweger et al, 1994). Kirchweger et al (1994) found LOH in 45.9% of informative tumours at the P53 locus and 58.8% at locus close to the tip of 17p.

LOH at 17p has been found to be independent of age (Fujii et al, 1998), but associated with high grade (Niederacher et al, 1997), high mitotic index (Callahan et al, 1993) and lymph node involvement (Takita et al, 1992).

#### Known genes of interest at 17p13.1

P53 is now classed as a tumour suppressor gene (see section 1.2.2) however it was initially studied in its mutated form and was thought to be an oncogene (Matlashewski et al, 1984; Lane and Benchimol, 1990). The P53 gene is located on the short arm of chromosome 17 at 17p13.1. P53 through its ability to detect DNA damage and once detected to activate pathways which inhibit cell division, and allow DNA repair, or apoptosis, helps maintain the integrity of the genome (Lane and Benchimol, 1990). Loss of function of the gene or its regulatory mechanism could lead to an increased accumulation of mutations, genomic instability and a resultant faster rate of tumourigenesis (Harris, 1996).

#### **4.1.4 TYPES OF GENETIC MARKERS**

A marker can only be considered informative for a given individual if it exists in the heterozygous state in the normal tissue. If the individual is constitutively homozygous LOH/AI is difficult to detect and the marker is considered to be non informative for that individual. Any genetic marker used therefore needs to be sufficiently polymorphic to ensure a reasonable rate of informativeness at the locus being studied. Several types of markers exist and may be used to study LOH/AI.

#### **Restriction Fragment Length Polymorphisms**

Use is made of changes close to the locus of interest which result in the variable occurrence of restriction sites. A deletion occurring would result in the loss of the site. After restriction of DNA with the relevant restriction enzyme gel electrophoresis will demonstrate fragments of different sizes, RFLPs. The presence or absence of the locus of interest is then located by Southern blotting (Southern, 1975) and hybridisation with a probe coding for the gene of interest (Lander and Botstein, 1980). However RFLP sites are not very polymorphic, a site is either there or it is absent, and the number and location of RFLP sites are limited.

#### Variable Number of Tandem Repeats

Variable Number Tandem Repeats (VNTRs) are regions of tandemly repeated DNA with each repeat being 11- 60 bp in length. Since the number of repeats may vary between individuals there are typically several alleles for any given VNTR site; this is a much higher level of polymorphism than found in the RFLPs and results in higher levels of informativity (Nakamura et al, 1987). Detection is usually by Southern blotting and hybridisation, although for the smaller repeats polymerase chain reaction analysis, PCR, is possible.

#### **Microsatellites or Short Tandem Repeats**

The polymorphism between short tandem repeats (STR) results from different numbers of repeated di, tri, or tetra nucleotides resulting in different lengths of DNA. Since their discovery STR have been much more widely used than either RFLPs or VNTR (Weber and May, 1989; Litt and Luty, 1989) because they are highly polymorphic and therefore more informative and also are spread widely throughout the genome. STR are analysed by PCR analysis using primers flanking the region of interest. The method is quicker than Southern blotting and hybridisation and requires less DNA.

#### **4.1.5 POLYMERASE CHAIN REACTION**

The discovery of the thermo stable DNA polymerases (Innis et al, 1988) and the development of the automated polymerase chain reaction procedure (PCR) (Mullis et al, 1986) has revolutionised research in molecular biology.

#### Simplified theory of the polymerase chain reaction system

PCR is an in vitro method for DNA synthesis, and enables the amplification of specified pieces of DNA, making analysis of even single copy target sequences possible (Saiki et al, 1988); the process is outlined in table 4.2.

#### Table 4.2 Summary of PRC process

| Components  | s required for the PCR  |  |  |  |  |  |
|-------------|---|--|--|--|--|--|
| • A source  | A source of template DNA  |  |  |  |  |  |
| • Reaction  | buffer supplying copies of the 4 nucleotides required for the synthesis of DNA in a     |  |  |  |  |  |
| suitable    | buffering system  |  |  |  |  |  |
| • Pair of o | ligonucleotide primers designed to hybridise to opposite strands flanking the region of |  |  |  |  |  |
| interest of | on the target DNA.  |  |  |  |  |  |
| • Taq poly  | merase, (thermostable DNA polymerase enzyme)  |  |  |  |  |  |
|             | CR reaction comprises of three phases:  |  |  |  |  |  |
| Pre PCR     | The template DNA is denatured at 95-98°C for at least 5mins                             |  |  |  |  |  |
| The         | The temperature cycles between three steps  |  |  |  |  |  |
| cycling     | 1.Denaturing, at 95°C ready for DNA synthesis.  |  |  |  |  |  |
| stage       | 2. Annealing; primers anneal to the complementary sequences on the template DNA.        |  |  |  |  |  |
|             | The temperature is dependent primarily on the primer sequence, temperatures above       |  |  |  |  |  |
|             | the optimal sequence result in more stringent hybridisation, lower temperatures         |  |  |  |  |  |
|             | allow less specific matching.   |  |  |  |  |  |
|             | 3. Extension; usually at 72° to allow synthesis of new DNA molecules. These new         |  |  |  |  |  |
|             | molecules are then denatured at the start of the next cycle and act as templates for    |  |  |  |  |  |
|             | the next round of amplification.  |  |  |  |  |  |
|             | These three steps are repeated as many times as required to achieve sufficient          |  |  |  |  |  |
|             | product although too many cycles can result in non specific background products.        |  |  |  |  |  |
| Final       | usually at 72°C, to allow completion of the reaction.                                   |  |  |  |  |  |
| extension   |   |  |  |  |  |  |

#### **Optimisation of the PCR reaction**

Optimisation to maximise both yield and specificity of product may be achieved by altering the proportion of the reagents in the reaction, and or the time and temperature parameters of the reaction. Some of the common optimisation strategies are outlined in table 4.3. and may involve one or all of the components.

| Component   | Action                          | Effect                                      |
|-------------|---------------------------------|---|
| Reaction    | • increase Mg <sup>2+</sup> ion | Lowers specificity                          |
| Buffer      | • increase nucleotides          |   |
| Taq         | • increase concentration        | Improves yield but excess may result in     |
| Polymerase  |                                 | non specific products                       |
| Primer      | • should balance eg dilute      | Improves yield                              |
| /substrate  | substrate/ low primer           | Excess primer may result in substrate       |
| ratio       | concentration                   | independent amplification "primer           |
|             |                                 | dimers".                                    |
|             | • "booster PCR"                 | Initial concentration of primers is low,    |
|             |                                 | but more are added after a few cycles.      |
|             |                                 | Improves yields for dilute substrates       |
| PCR cycling | • increase number of            | Improves yields but also may increase       |
| parameters  | cycles                          | non specific amplification.                 |
|             | and/or increase steptime        | Higher temperature, more specificity but    |
|             | • Annealing temperature         | lower yield.                                |
|             |                                 | At least one essential component is         |
|             | • "Hot start PCR"               | omitted from the hybridisation tube, until  |
|             | (Erlich et al, 1991; Ruano      | after the DNA denaturing step.              |
|             | et al, 1992).                   | Annealing temperature starts 5-10°C         |
|             | • "Touch down PCR"              | above optimal for the primer pair and       |
|             | (Don et al, 1991)               | then reduces by $0.5-1$ °C /cycle until the |
|             |                                 | optimal temperature is reached and then     |
|             |                                 | continues for the remaining cycles.         |
|             |                                 |   |
|             | <u> </u>                        | I   |

 Table 4.3 General optimisation strategies for PCR

#### **Precautions**.

It is possible for single copies of a DNA region to be amplified to approximately  $6x10^9$  molecules/µl (Saiki et al, 1988). With such sensitivity it is obvious that any source of extraneous DNA contamination could result in erroneous results. A particular problem is that of cross contamination between samples before the amplification is complete and care must be taken to avoid it at all stages. Stringent care is necessary especially if the quantity template DNA/reaction tube is small since any contaminant DNA could swamp out the test material.

| Potential sources<br>of contamination | Methods of avoiding contamination                                     |  |
|---------------------------------------|---|--|
| Extraneous DNA                        | • Disposable latex gloves should be worn at all stages of sample      |  |
|                                       | preparation, processing, and analysis and changed regularly.          |  |
| Cross                                 | • Physically separating the laboratory areas for all procedures up to |  |
| contamination                         | and including PCR (Orrego, 1990).                                     |  |
| between sample                        | • Each work area should have its own set of micropipettes             |  |
| batches                               | • Effect of any contamination can be limited by aliquoting all        |  |
|                                       | reagents used for sample preparation and PCR reaction                 |  |
| Cross                                 | • Care in preparing samples to avoid cross contamination              |  |
| contamination                         | (precautions varying according to the source and nature of the        |  |
| between samples in                    | template).  |  |
| the same batch.                       | • Avoiding the creation of aerosols containing template while         |  |
|                                       | handling and opening eppendorfs during the PCR set up and             |  |
|                                       | pippetting.   |  |
|                                       | • Use of fresh disposable micro pippette tips for each solution and   |  |
|                                       | each tube once the tube contains sample or PCR product                |  |

| Table 4.4 | <b>Basic precautionary</b> | measures to limit t | he risk of contamination |
|-----------|----------------------------|---------------------|--------------------------|
|           |                            |                     |                          |

#### Monitoring for contamination

Use of a negative control is necessary to ensure that no contamination has occurred during the processing of a particular batch. The control should contain all the components necessary for the PCR reaction but should lack template DNA, this tube should be the last of the batch to be set up to maximise the risk of contamination.

#### Use of paraffin embedded tissues as a source of DNA template

Despite the extra care that must be taken to avoid cross contamination during extensive manual manipulation of the samples when cutting, dewaxing etc routinely fixed sections are excellent PCR substrates (Shibata, 1994). PCR amplification from formalin fixed, paraffin embedded tissue has advantages. Amplification is possible from a single 10µm section or less and so is much more conservative than DNA extraction followed by Southern blot analysis which requires much more starting material. Use of routine fixed, embedded tissue makes possible retrospective studies, which is particularly important when studying a disease with a low incidence rate.

There are some disadvantages in using DNA from such material as a template (Wright and Manos, 1990). Formaldehyde fixation results in breakage of the DNA so that sequences longer than 650 bp are rarely amplifiable and there may be more non specific amplification than with DNA from unfixed material. Shibata (1994) suggests 80-170bp as being the optimal size for PCR targets. The amplification process may be less efficient due to traces of chemicals remaining from fixation and extraction, for example NP40 a non-ionic detergent used during extraction has an inhibitory effect on Taq polymerase even at 0.1% (Kawaski, 1990). Cell debris may also inhibit amplification, but this can be limited by centrifugation after extraction, with dilution of the resulting supernatant.

#### Microdissection

By using tissue sections stained with haematoxylin and eosin as a guide it is possible to selectively remove areas of interest and to use this material for amplification, rather than the whole section. This technique may then either be used to investigate specific or multiple areas of the tumour, or to enrich the sample.

#### **4.1.6 GEL ELECTROPHORESIS**

When considering the separation of a double stranded DNA product, as is the case in LOH analysis, the choice of agarose or polyacrylamide as the matrix on which the product is separated is mainly dependent on the resolution required between the expected bands.

#### Electrophoresis and gel visualisation

Love et al (1990) working with microsatellite polymorphisms in mice stated that approximately 50% of alleles were resolvable by agarose gel electrophoresis, when the size difference was 8-base pairs or greater. The same group (Todd et al,1991) used 4% agarose gel electrophoresis and only if no size variation was found did they repeat the sample on 6-10% non denaturing acrylamide gels, which can resolve size variation of 2 base pairs or greater. The gels were visualised using ethidium bromide or silver staining, both having the advantage of being non isotopic.

Although the majority of papers studying microsatellite markers in humans have used denaturing PAGE with isotopic labelling, others report the use of non denaturing PAGE (Bethwaite et al, 1995; Koreth et al, 1995; Martinelli et al, 1996; Lahiri et al, 1997), all of whom used ethidium bromide as the means of band visualisation. The avoidance of isotopically labelled nucleotides enables non denaturing gels to be used. The incorporation of the radioactive nucleotide in the PCR product induces partial strand separation (Weber and May, 1989), and it is preferable therefore that the strands are made to separate completely by denaturing and loaded on a denaturing gel in order to give consistent and comparable results.

#### Interpretation of results

Non denaturing PAGE may also produce extra bands, but use of a molecular size DNA ladder on all gels allows identification of the bands of interest. Another problem common to all LOH studies, regardless of the type of gel chosen, is when alleles are apparently only partially lost. This is usually due to the tumour sample containing a significant proportion of normal cells and has been greatly helped by the introduction of microdissection techniques (section 4.4.3). It is not however possible to resolve this problem completely in all cases and the decision of LOH or retention has to be done on the basis of relative signal strength..

#### Densitometry

Densitometry provides an independent quantitative method for assessing LOH and is useful in cases of incomplete loss particularly when the relative strengths of the normal and tumour sample vary (Orphanos et al, 1995; Stratton et al, 1995). Calculation of relative ratios was basically the same in all reports.

T:N

#### where T = t1/t2 and N = n1/n2

t1, t2, n1, and n2 being the intensities of alleles 1 and 2 in tumour and normal tissue samples respectively. A ratio less than 0.5 or more than 2.0 was taken as evidence for AI (Bethwaite et al, 1995; Koreth et al, 1995; Orphanos et al, 1995; Munn et al, 1996; Noviello et al, 1996). Bonsing et al (1993) took 1.4 as the cut off to allow for cases where there had been

allelic gain of a copy and up to 40% normal cells in the tumour sample. In addition Bonsing et al (1993) commented that when scored by eye 1.4 is usually perceived as retention whereas greater than 1.4 would be considered AI.

Some studies utilising microdissection techniques have found that densitometry is no longer necessary due to the improved selection of tumour and normal samples (Fujii et al, 1996; Chappell et al, 1997).

# **4.2 AIMS**

The aims of this chapter are to

- Establish in the Jeddah laboratory a non isotopic technique to screen for loss of heterozygosity in the three study populations at the selected chromosomal locations.
- To test whether there are significant differences between the three study groups for the selected genetic markers.
- To test whether there are significant differences between the different age groups for the selected genetic markers.

## **4.3 MATERIALS**

#### 4.3.1 Tissues

For each case, selected using criterion as in 3.4.1, sections of tumour plus a section including normal tissue for use as a source of constitutional DNA were identified. For the majority of cases the source of normal tissue comprised lymph nodes with no evidence of metastasis, selected by Dr Walker. When such lymph nodes were not available skin from the nipple was used as the source of normal cells. In two cases tissue from earlier surgery was utilised as the source of normal cells, namely cervix, and fallopian tube. In one case non involved breast tissue had to be used as the source of normal cells.

Samples from the archival blocks could not be taken from all the identified patients either because of unavailability, or if only a limited amount of tissue remained. Tonsil fixed and processed in a similar manner, was used for technique development.

#### 4.3.2Primers

Requirements were that the primers studied should be highly polymorphic loci mapping to the regions of interest (4.1.4). Also, because the study involved comparison of LOH in the three groups at different ages rather than a search for new candidate tumour suppressors, the primers had to map to regions already established as sites of known LOH in breast cancer from previous studies.

Five primer pairs were selected, (table 4.5) being situated at the three sites described in section 4.1.1.

| Table 4.5 | Selected | primers |
|-----------|----------|---------|
|-----------|----------|---------|

| location | primer                           | sequence                       | size of    |
|----------|----------------------------------|--------------------------------|------------|
|          |                                  |                                | product in |

#### 4.3.3 Chemicals

The recipes for the buffers and chemicals used, with suppliers of the individual components, are listed in appendices B and C.

### **4.4 METHODS**

Although PCR analysis of DNA purified from blood haemoglobinopathy studies had been performed previously in the Jeddah laboratories no LOH studies using fixed embedded tissue as the source of DNA had previously been undertaken. It was therefore necessary to establish and validate the techniques.

#### **4.4.1 LABORATORY SETUP**

A heated top PCR machine was chosen (Perkin Elmer 2400) to avoid the use of oil and for its faster ramp time and versatile programming capabilities. The work area was set up using the precautions outlined in table 4.4 to limit sources of possible contamination. Gel preparation and electrophoresis was performed using the Bio Rad Protean II apparatus which has a coolant core enabling the gel to be kept at a uniform temperature. After experimentation it was found that a 25 well 0.5mm comb was the most suitable allowing adequate space for up to 60µl of product and enabling up to 12 pairs of patient samples to be analysed on a gel.

Before processing material from the study groups the following preliminary experiments were performed.

All procedures were optimised initially on tonsil before repeating, and reoptimising where necessary, on breast tissue.

Validation of technique was achieved by

- successfully repeating results previously obtained by myself during a training session in the laboratories in Leicester.
- repeating results, previously obtained using purified DNA, when using a crude extract as a PCR template.

Since it was not always possible to process samples immediately reproducibility over time was tested by

• repeating results previously obtained with freshly cut material and with the same material after storage at -4°C for several months.

#### **4.4.2 SAMPLE COLLECTION**

Sections from Leicester were selected by Dr Walker, cut and packed in tubes or placed on slides by Sheila Dearing. Sections from Jeddah were located from the records by myself, checked by Dr Walker, and cut by the histology technician at each of the hospitals (named individually in acknowledgements), while I assisted in keeping the area cleaned with xylene, decontamination of knives and packing sections into tubes or collecting them onto slides. Tonsil sections for the set up procedure were routinely fixed and then cut and packed into tubes or onto slides by myself.

Sections were cut from the previously selected blocks following stringent isolation precautions to avoid cross contamination between blocks or from external sources.

1. Gloves were worn through out the procedure, and changed frequently.

2. The microtome blade, the microtome, and surrounding work bench area were cleaned between blocks with xylene.

3. The water bath, used for floating sections onto slides, was swept clean of all debris between blocks.

From each block one 4µm section and two 10µm sections were cut serially onto glass microscope slides. In addition two 10µm sections were cut into screw top sterile eppendorf tubes.

#### 4.4.3 SECTION STAINING AND CRUDE MICRODISSECTION

This was used to obtain normal tissue and to remove normal tissue adjacent to a tumour. After being floated onto glass slides the sections were allowed to drain and then were incubated at 37°C for 3 hours. Slides were then processed as follows:

- Sections were then dewaxed in xylene (1x5mins, 1x2mins)
- rehydrated by passing through a series of graded alcohols (2x2min 99%, 2x2mins 95%)
- rinsed in running tap water (1x5mins)

The  $4\mu m$  slide sections were then

- stained with haematoxylin (1x1min)
- rinsed in running water (1x5mins)
- stained in eosin (1x15secs), to complete the H&E stain.

The 10µm slide sections were

• stained with eosin (1x1sec).

Both types of section were then

• dehydrated back through the alcohol series

4µm H&E sections were taken back through xylene prior to mounting in resinous mountant

(XAM), 10µm sections were left unmounted.

The H&E sections were examined by Dr Walker, and areas for crude microdissection identified.

The microdissection was as described by Koreth et al (1995) and as modified by Munn et al (1996). Using the H&E section as a guide the required region was located on the eosin stained section by means x40 magnification with a dissection microscope (James Swift Prior dissection microscope). Once located the required region was microdissected out using a drawn glass capillary tube. Some trouble was found on some days with static electricity making dissected product hard to handle, when this occurred it was advantageous to introduce a drop of alcohol into the bottom of the capillary tube. The tube together with the microdissected material were broken off into a sterile eppendorf tube. Using this method it was possible to enrich tumour samples when the section contained large amounts of normal breast cells and or stroma. Also when no unaffected lymph node was available, normal skin or normal breast cells could be microdissected, care being taken to select skin or cells as far away as possible from the tumour.

#### 4.4.4 DNA EXTRACTION

Procedures used were those practised at the Glenfield Hospital Breast Cancer Research Unit in Leicester, where I under went 6 weeks training.

The initial step in preparing the whole tissue sections for PCR amplification is removal of the wax. Sections were

1. incubated at room temperature in 1ml of xylene for 10mins.

2.centrifuged for 5 mins at 13,000 rpm and the supernatant discarded.

3. steps 1 and 2 were repeated was repeated with xylene, and then twice with absolute ethanol.

4. The tissue pellets were then allowed to air dry.

Microdissected tissue was already dewaxed and did not require any treatment prior to digestion.

Experiments were performed to compare varying amounts of digestion buffer, overnight (18hr) or over the week end (48hr) digestion, and with or without oil. The protocol adopted was as follows:

- 400µl of rapid digestion buffer was added to the whole sections in eppendorfs
- 200µl of microdissection rapid digestion buffer to the microdissected samples
- incubated over night at a temperature of 56°C to yield crude DNA extracts.

- heated the following morning to 95°C for 10mins to inactivate the proteinase K
- microcentrifuged to pellet any undigested tissue debris
- aliquots were taken for PCR amplification.

Typically  $10\mu$ l was taken from microdissected samples. Whole section digests were diluted 1:10 with distilled water and  $10\mu$ l used for each PCR reaction. Unused digests were stored at  $-20^{\circ}$ C.

#### 4.4.5 DNA AMPLIFICATION

The quality of each digest was tested using GAPDH, a housekeeping gene readily amplified. This was necessary since it was not possible to process the sections immediately after cutting and some of the sections had been stored several months prior to extraction.

#### Amplification conditions and optimisation

Each primer pair were amplified generally in accordance to the optimum conditions previously established at the Leicester laboratory. Initially test breast DNA was amplified using these conditions,  $15\mu$ l of the product run on a 2% Nu sieve agarose gel in TBE buffer at 80V for 1.5 - 2hr hrs, and visualised by staining with ethidium bromide. The set up and PCR conditions were modified if necessary until a sharp band was obtained. The typical PCR reaction was as follows

10μl DNA extract
6μl reaction buffer
1μl forward primer (10pm/μl)
1μl reverse primer (10pm/μl)
1.5μl Taq (1unit/μl)
water to total reaction volume of 60μl

The amplification conditions are outlined in table 4.6

Table 4.6 Optimised cycling stage parameters

| Stage      | Primer          | Conditions  |
|------------|-----------------|---|
| Denaturing | all primers     | 96°C for 7 mins   |
| Cycling    | ERTA,           | (94°C x 1min + 56°C x 1 min + 72°C x 1.20 min)  |
| conditions | D6S186          | 35 cycles   |
|            | D6S193          | (94°C x 1min + 57°C x 1 min + 72°C x 1.20 min)<br>35 cycles   |
|            | D16S413         | (94°C x 1min + 65°C x 1 min(minus 0.5°C each cycle) +<br>72°C x 1.20 min) 10 cycles<br>+(94°C x 1min + 60°C x 1 min + 72°C x 1.20 min)<br>25 cycles |
|            | P53(AAA<br>AAT) | (94°C x 1min + 64°C x 1 min + 72°C x 1.20 min)<br>35 cycles   |
|            | GAPDH           | (94°C x 1min + 60°C x 1 min + 72°C x 1.50 min)<br>35 cycles   |
| Elongation | all primers     | 72°C for 7 mins followed by a hold at 4°C   |

#### **Testing for LOH**

Once conditions for each primer had been optimised and sample quality had been verified crude extracts from the samples were amplified with each of the 5 primer pairs. Five sample pairs, comprising normal and tumour DNA extract from each individual and a negative control (with no DNA template added) were amplified in each PCR run and the products run on 2% Nuseive agarose gels, TBE buffer at 80v for 2hrs, to check for evidence of amplification.

The amplified sample product was then run on 12% non denaturing 19:1 polyacrylamide gel at 4°C and 8Watts in 1xTBE buffer, using the BioRad Protean II apparatus. Approximately 60µl of sample and loading buffer (2:1) was loaded into each well, and a molecular size ladder was included on each gel.

#### 4.4.6 DNA VISUALISATION

The position of the amplified DNA was visualised on the gel by staining with ethidium bromide  $(0.5\mu g/ml)$  for 30-35 mins. Photographs were then taken by AbduRahiman Pattani using the a Polaroid 545 Land Camera and black and white polaroid films (Polaroid Positive-Negative film 55). The negatives were treated with 18% sodium sulphite solution and rinsed thoroughly with distilled water for five minutes.

#### 4.4.7 ANALYSIS

#### **Interpretation of gels**

The position of the bands in each sample pair was examined and scored either as

- 1. Non informative (NI) where the normal DNA was homozygous for the marker.
- 2. Retained (R) where neither bands were lost or reduced.
- 3. Heterozygosity (LOH) where a band was lost or markedly reduced in intensity.

Examples, for each of the primers tested is presented in fig 4.1. Scoring of LOH is prone to a high degree of inter observer variability and it is therefore advisable to have at least two persons scoring the gels independently to confirm results. However since no one was available in Jeddah to act as a second scorer the following procedure was adopted to help increase the reliability of the results. Scoring was done up to four times, on the gel, the print, and the negative, and finally with a densitometric reading of the negative. Due to the signal strength and or quality of the negative it was not possible to perform densitometric analysis on all samples. However those samples which did not produce clear results, at least on the gel, were repeated.

#### Analysis

- Summary tables of loss of heterozygosity, and informativeness were compiled, and overall LOH with respect to informativeness was compared using  $\chi^2$  analysis.
- Cases were assessed by the number of primers showing LOH in relationship to the number of informative markers. The distribution of LOH with respect to number of informative sites was compared between the three groups using Pearsons correlation coefficient using Minitab 11.
- Pearsons correlation coefficient was calculated between the three markers tested on 6q for each of the study groups and for pooled data from all three groups.
- Age, grade, lymph node status, and size which have been found in some earlier studies to vary significantly with LOH at various loci were analysed with respect to age and ethnic group. Pooled data from 6q, data from 16q and 17p were all tested.

| Primer  | Retained            | LOH                               | Non-informative |
|---------|---------------------|-----------------------------------|-----------------|
| D6S186  | TN                  |                                   | non<br>present  |
| D6S193  | T N<br>ratio = 1.02 |                                   | non<br>present  |
| ERTA    | T N<br>ratio = 1.2  | $T N$ $\rightarrow$ $ratio = 2.7$ |                 |
| D16S413 | TN                  | ratio = 3.8                       | T N             |
| р53     |                     | T N $ratio = 2.0$                 | TN              |

Fig 4.1 Examples of LOH and informativity for each of the loci analysed

-> LOH

### **4.5 RESULTS**

#### 4.5.1 SUMMARY DATA

Table 4.7 presents the summary data for the molecular study. Percentage informativity varied from primer to primer and population to population. The percentage of LOH is lowest for all the markers in the AL group. AA has the highest LOH for markers D6S186 and D16S413, with EL having the highest percentage LOH for the other markers.

| Group | Primer  | (n)  | loh/inf | %LOH  | %inf   | Total LOH<br>/Total inf |
|-------|---------|------|---------|-------|--------|-------------------------|
| AA    | erta    | (95) | 33/80   | 41.25 | 84.21  | 0.36                    |
|       | D6S193  | (93) | 24/69   | 26.00 | 100.00 |                         |
|       | D6S186  | (95) | 19/76   | 20.00 | 100.00 |                         |
|       | P53     | (95) | 28/44   | 63.64 | 46.32  |                         |
|       | D16S413 | (94) | 36/76   | 47.37 | 80.85  |                         |
| AL    | erta    | (35) | 10/28   | 35.71 | 80.00  | 0.27                    |
|       | D6S193  | (34) | 8/26    | 24.00 | 100.00 |                         |
|       | D6S186  | (34) | 6/28    | 18.00 | 100.00 |                         |
|       | P53     | (35) | 7/16    | 43.75 | 45.71  |                         |
|       | D16S413 | (35) | 4/20    | 20.00 | 57.14  |                         |
| EL    | erta    | (47) | 19/39   | 48.72 | 82.98  | 0.36                    |
|       | D6S193  | (45) | 12/33   | 26.67 | 100.00 |                         |
|       | D6S186  | (46) | 7/39    | 15.22 | 100.00 |                         |
|       | P53     | (47) | 21/29   | 72.41 | 61.70  |                         |
|       | D16S413 | (47) | 15/45   | 33.33 | 95.74  |                         |

Table 4.7 Summary data for molecular study

A  $\chi^2$  test of the total LOH/total informative for each group resulted in a calculated  $\chi^2$  value of 2.27 at 2 degrees of freedom which is less than the critical value of 5.99, indicating that there is no significant difference between the three groups. 4.5.2 ASSESSMENT OF THE NUMBERS SHOWING LOH IN

# RELATIONSHIP TO THE NUMBER OF INFORMATIVE MARKERS.

No cases were totally uninformative (0/0) and few had total LOH and were totally informative (5/5) (table 4.8). More cases of AA (38.95%) and AL(48.57%) had LOH at one site rather than two (AA 25.6%, AL 17.14%), whereas EL had 38.3% of cases with LOH at two sites compared with 23.4% with LOH at only one site.

|       |     |     |     |     | B   |     |     |     |     |     |     |     |     |     | (-  |     |     | ive ma |     |     |     |

Table 4.8Primers showing LOH in relationship to the number of informative markers

•

Pearsons correlation analysis on this data results in:

The critical value is 0.44 at 18 df, correlation of AA and AL equals 0.6 (significant), AA and EL 0.8 (significant), and AL and EL 0.38, failed to reach statistical significance.

### 4.5.3 ANALYSIS OF SELECTED CLINICO-BIOLOGICAL PARAMETERS WITH MARKER SPECIFIC LOH

Age, grade, lymph node status and tumour size <2cm>, were further analysed within each of the study groups for the markers on 6q, 16q, and 17p

#### 6q

#### Correlation between LOH and the three markers on 6q

Table 4.9 presents the results of Pearsons correlation between LOH or no LOH in each of the three markers tested on 6q for each of the study groups and for the pooled data of all three study groups. No significant correlation was found between the three markers tested on chromosome 6.

# Table 4.9Pearsons correlation between LOH or no LOHin each of the three markers tested on 6q

| Group          | ERTA+D6S193 | ERTA+D6S186 | D6S193+D6S186 | Comparison<br>with tabulated<br>critical value |
|----------------|-------------|-------------|---------------|--|
| AA             | -0.19       | 0.01        | -0.08         | < 0.35 at 26 df<br>not significant             |
| AL             | 0.1         | -0.09       | -0.39         | < 0.58 at 10 df<br>not significant             |
| EL             | -0.42       | 0.17        | 0.42          | < 0.81 at4 df<br>not significant               |
| pooled<br>data | -0.13       | 0.02        | -0.09         | < 0.35 at 46 df<br>not significant             |

In the assessment of LOH with clinico-biological parameters all three markers were considered together as presence or absence of LOH on chromosome arm 6q.

LOH with respect to age was also assessed for each marker individually.

| Group | Age group           | LOH | No LOH | % LOH | $\chi^2$ analys critical va | is compared to<br>lue of 3.8 |

#### Table 4.12LOH at 6q in different age groups with reference to selected clinicopathological parameters

- Comparing combined markers
  - There was a significant difference in LOH 6q between pre and post menopausal cases in the AA study group
  - Generally AA had a higher percentage of LOH in the younger groups. In AL and EL there was higher LOH in the older groups.
  - There was no significant difference when the three study groups were compared for any of the age groupings
- Comparing individual markers
  - ERTA showed more LOH in the older groups of EL and significantly less in the under 44 years, whereas AA had more LOH in the younger groups.
  - Both AA and EL had more LOH at D6S193 in the younger groups. The difference was significant in AA.
  - D6S186 showed little difference with age in either AA or EL.

#### Lymph node status

- There was no significant difference in LOH with node status for any of the study groups for combined ages.
- In AA there was a significant difference between the frequency of LOH found in LN+ tumours in the pre menopausal cases compared to post menopausal. (χ<sup>2</sup> =5.5, d.f.=1, p<0.025) pre menopausal cases had more LOH.</li>
- LN+ tumours in the AL and EL tended to have more LOH in the older groups.

#### Size

- For combined age groups there was no significant difference with size for any of the study groups.
- A significant difference was found for LOH in tumours over 2cm between the pre and post menopausal groups in AA, (χ<sup>2</sup>=4.2, d.f.=1, p<0.05), pre menopausal cases exhibiting more LOH. Whereas in EL LOH for both pre and post menopausal, over 2cm, were the same, although it should be noted that the number of cases was small.</li>

#### Grade

• For combined ages, EL showed significantly more LOH in the grade 3 cases than the grades 1&2 ( $\chi^2$ =3.9, d.f.=1, p<0.05). AA and AL had more LOH in grades

1&2 than in grade 3 cases, although the differences were not statistically significant.

• In grade 3 cases in AA there was significantly more LOH in the pre menopausal age group than the post menopausal group ( $\chi^2$ =4.3, d.f.=1, p<0.05).

Table 4.13 LOH at 16q in different age groups

#### Age

- AA, AL and EL all showed greater LOH at 16q in the older age groups but differences were not significant.
- There was a significant difference between AA and AL overall (χ<sup>2</sup>=4.87, d.f.=1, p<0.05), and in the post menopausal (χ<sup>2</sup>=4.4, d.f.=1, p<0.05) and over 44 years age groups.</li>

Table 4.14 LOH at 16q in different age groups with reference to selected clinicopathological parameters

Lymph node status

- EL had more cases showing LOH at 16q in lymph node positive cases compared to lymph node negative cases (χ<sup>2</sup>=5.69, d.f.=1, p<0.025). Neither AA or AL showed a significant difference.
- AA, AL and EL had a higher percentage of LOH in node negative cases compared to node positive cases for the younger groups. However older groups all showed a higher percentage of LOH in the lymph node positive tumours.
- In AA there was very little difference between the age groupings for the percentage of LOH in lymph node negative tumours. However there were significant differences in the lymph node positive cases between pre and post menopausal cases (χ<sup>2</sup>=4.78, d.f.=1, p<0.05), and cases under and over the age of 44 (χ<sup>2</sup>=6.78, d.f.=1, p<0.025).</li>

Size

- EL showed significantly more LOH at 16q in tumours over the size of 2cm (χ<sup>2</sup>= 9.2, d.f.=1, p<0.05). AA however had a higher percentage of LOH in tumours less than 2cm, although the difference with size was not significant.</li>
- Both AL and EL had more LOH in the cases with tumours over 2cm (the numbers in AL are very small).
- The older age groups in AA had more frequent LOH in the larger tumours whereas for the younger groups it was in the smaller tumours. There was significantly more frequent LOH in tumours over 2cm in both the post menopausal (χ<sup>2</sup>=5.37, d.f.=1, p<0.025) and over 44 years (χ<sup>2</sup>=8.37, d.f.=1, p<0.005) age groups compared to the younger groups.</li>

#### Grade

- There was no significant difference in LOH between grade 1&2 and grade 3 tumours, when all ages were considered together.
- AA and AL showed more LOH in the grade three cases. There was no assessment of AL under 44 years due to the absence of LOH.
- EL had more LOH in grade 3 cases in the older groups but more LOH in the younger groups in grade 1&2 tumours.

#### 17p

Table 4.15 LOH at 17p in different age groups

| Group | Age group       | LOH | No<br>LOH | % LOH | $\chi^2$ analysis compared to critical value of 3.8 |
|-------|-----------------|-----|-----------|-------|---|
| AA    | All             | 28  | 16        | 63.6  |   |
|       | pre menopausal  | 17  | 8         | 68    | 0.13 Same   |
|       | post menopausal | 11  | 8         | 57.9  |   |
|       | under 44 years  | 16  | 2         | 88.9  | 8.39 Different                                      |
|       | over 44 years   | 12  | 14        | 46.2  |   |
| AL    | All             | 7   | 9         | 43.8  |   |
|       | pre menopausal  | 1   | 5         | 16.7  | 2.86 Same   |
|       | post menopausal | 6   | 4         | 60    | (small numbers)                                     |
|       | under 44 years  | 1   | 2         | 33    | 0.16 Same   |
|       | over 44 years   | 6   | 7         | 46.2  | (small numbers)                                     |
| EL    | All             | 21  | 8         | 72.4  |   |
|       | pre menopausal  | 10  | 3         | 76.9  | 0.24 Same   |
|       | post menopausal | 11  | 5         | 68.8  | (small numbers)                                     |
|       | under 44 years  | 8   | 1         | 88.9  | 1.77 Same   |
|       | over 44 years   | 13  | 7         | 65    | (small numbers)                                     |

Age

- In AA and EL more frequent LOH at p53 was seen in the younger age groups, and the difference in AA under and over 44 years was statistically significant (χ<sup>2</sup>=8.39, d.f.=1, p<0.005).</li>
- AL had more LOH in older age groups than younger groups (numbers of cases small).
- Both AA and EL showed a high percentage of LOH in the under 44 years group (88.9%).

### Table 4.16 LOH at 17p in different age groups with reference to selected clinicopathological parameters

#### Lymph node status

- AL had more frequent LOH in lymph node negative tumours when all ages were considered together (numbers too small for statistical analysis). EL also showed more LOH in lymph node negative cases but the difference was not statistically significant. Analysis was not possible for AA since there were no lymph node negative cases without LOH.
- In all age groups in AA, AL and EL lymph node negative tumours had a higher percentage of LOH.
- For AA and EL percentage LOH in lymph node positive cases appeared to be similar in post and pre menopausal cases, but higher in the lymph node positive cases under the age of 44 years compared with those over 44 years (numbers were too small to perform a  $\chi^2$  analysis).
- Size
- There was no significant difference in LOH at p53 with size when all ages were considered together.
- For all age groupings of AA and EL there was more LOH in tumours over 2 cm. In AL only younger age groups had more LOH in the larger tumours (very small number of cases).

#### Grade

- For combined age groups, AA had a higher percentage of LOH at p53 in grade 3 tumours whereas both AL and EL had more frequent LOH in grade 1&2 tumours. Numbers were too small to allow  $\chi^2$  analysis.
- For all age groupings in EL there was a higher percentage of LOH in grade 1&2 tumours. Younger age groups of AA also had a higher percentage of LOH in grade 1&2 tumours, but older age groupings had more LOH in grade 3 tumours. The opposite was observed in AL, with more LOH in grade 3 tumours in younger age groups, and more LOH in grade 1&2 tumours in the older age groups (number of cases was small).

### **4.6 DISCUSSION**

Differences in clinico-biological markers studied between the three study groups with respect to age and/or ethnicity have been demonstrated in chapter 3. The aims of this chapter were to set-up non isotopic techniques to screen for LOH. In order to enable an investigation of possible genetic variation with respect to age and ethnic origin.

#### **4.6.1 METHODOLOGY**

#### **Preparation of DNA template**

Purified DNA was used in preliminary experiments, but after testing for reproducibility crude extracts were used in all later experiments (section 4.4.4). The use of crude extracts reduced the preparation time by more than half and therefore reduced the time required to process the samples. Crude extracts appeared to inhibit the PCR reaction slightly causing a lower yield. However this was overcome by increasing the amount of product loaded, and the value of the time saved resulted in crude extracts being the template of choice.

#### Signal detection

Three main factors influenced the selection of a non-isotopic protocol : Firstly non-isotopic methods carry less risk than those utilising radioactive isotopes. This was particularly relevant since the laboratory where I did my experiments was not at that time using any radio-active sources and consequently the necessary safety and disposal protocols for handling radioactive compounds were not present. The ability to obtain a regular supply of radioactive isotopes in good condition was also a factor. Most molecular grade chemicals need to be imported, and estimated delivery times of 10-24 weeks are the norm for non-isotopic material. Radioactive material would take at least as long. Finally a non- isotopic protocol enables the use of an oil free PCR protocol using small thin walled eppendorf tubes. These tubes allow for shorter ramp times and faster PCR runs, but are unsuitable for use with radiolabelled compounds.

An additional advantage was that avoiding the use of radio labelled nucleotides allowed the use of non-denaturing PAGE (section 4.1.6). It was found that this made it easier to use double gels on the Bio-Rad Protean II apparatus, with a large number of wells, since the need to maintain the sample in the denatured state during running was avoided. Although non-denaturing gels take longer to run, more samples could be processed.

#### **4.6.2 RANDOMISATION OF SAMPLES**

Great care was taken to analyse a mixture of cases from Jeddah and Leicester at the same time; starting from the digestion process through to gel interpretation, and to use a labelling method that anonymised them. Therefore during the PCR and gel analysis it was not possible to identify the age or ethnic origin of the samples so reducing the possible bias in gel interpretation.

#### **4.6.3 FINDINGS**

#### Summary data

Percentage informativity for each marker varied between the three study populations, this being a reflection of different patterns of polymorphisms within the populations. Percentage informativity was notably high (100%) for markers D6S186 and D6S193 in all three study populations. Similar differences can be seen in the literature eg. percentage informativeness of marker ESR is quoted as 82% (del Senno et al, 1992), 70.2% (Iwase et al, 1995), and 56% (Chappell et al, 1997).

Although  $\chi^2$  analysis showed no significant difference in the overall percentage of LOH between the groups, LOH of individual markers varied between groups. ERTA

EL had the highest percentage LOH (48.72) and AL the lowest (35.7) with AA having an intermediate value (41.25). The figures are in a similar range to the study of early invasive tumours (40.6%) (Chappell et al, 1997) but are higher than the 19.1% reported by Iwase et al (1995).

#### D6S193

Percentage LOH ranged from 24% in AL to 27% in EL, AA again being intermediate at 26%. These are similar to the percentages reported in the literature of 27.5 % (Orphanos et al, 1995), 39%, but are lower than those reported by Chappell et al (1997).

#### D6S186

AA had the highest LOH (20), EL the lowest (15), with AL intermediate (18), which are similar to the 20% described by Orphanos et al (1995) but lower than the 29% recorded by Chappell et al (1997).

#### D16S413

AL exhibited 20% LOH, EL 33.3% and AA 47%. The latter two compare with 46% LOH at D16S413 reported by Skirnisdottir et al (1995) and 36% for early invasive tumours (T.Walsh Doctoral Thesis, University of Leicester).

AL had a LOH of 43.8%, AA 63.6% and EL the highest at 63.6%. A range of results have been found by others at the p53 locus 68% (Munn et al, 1996), 45.9% (Kirchweger et al, 1994), and 29.3% (Schmutzler et al, 1997).

Considering that studies in the literature vary from those presented in this thesis, both in terms of age structure and /or ethnic make up, the results from within the three study groups are similar to those published. However this gives no information about the distribution of LOH with respect to the number of informative markers. Pearsons correlation analysis found a correlation between AA and AL, and AA and EL, and between AL and EL. Which might be expected, since if there are more informative cases the chances of having LOH are greater. AA and AL having the closest correlation.

An interesting observation was that EL had more cases with 2 instances of LOH whereas AA and AL had more cases with LOH at only one marker. Increased incidence of LOH has been correlated with greater tumour size (Nagayama and Watatani, 1993; Kerangueven et al, 1997), suggesting a time factor allowing more growth, genetic instability and tumour progression. However I demonstrated in chapter 3 that AA and AL tumours are bigger than those found in EL. This suggests possible genetic differences between the three study groups. The nature of these differences would require further investigation with more cases and a larger panel of markers.

#### Correlation of LOH for different markers on chromosome arm 6q

Since no correlation was found between LOH for the markers in the primers tested on chromosome arm 6q it was assumed that LOH at these three sites occurs independently. Data from the three loci was pooled to form combined LOH for chromosome arm 6q.

#### LOH and selected clinico-biological parameters

#### Age

AL and EL all exhibited a higher frequency of LOH at 16q in the older age groups, although the differences failed to reach significance. Relationship with age varied between markers. For example, at p53 LOH in AA and EL was higher in the younger age groups especially in the under 44 years age group. Apparent ethnic differences also exist, with AL and EL having higher LOH at 6q in the older age groups, whereas AA had more LOH premenopausally, although all fail to reach statistical significance. Examining the three markers separately LOH at ERTA showed the same pattern as for the combined markers. D6S193 however had more LOH in younger age groups in both AA and EL, suggesting age related differences at a molecular level irrespective of study group. Whereas D6S186 appeared to show little difference in LOH with age for either AA or EL. Findings for EL at the ERTA locus concur with those of Iwase et al (1995). This study, patients from London, found significantly more LOH at ESR in postmenopausal cases compared to premenopausal. *Lymph node status* 

For LOH at 6q there was no significant difference between LN+ and LN- when all ages were considered together. Other studies also found no significant difference in LOH at 6q when LN+ and LN- tumours were compared (Iwase et al, 1995; Noviello et al, 1996), although Devilee et al (1991) did find an association between the number of involved lymph nodes and LOH at 6q.

There was however a significant difference in LOH at 16q for EL ( $\chi^2$ =5.69, d.f.=1, p<0.025) with LN+ tumours having more LOH. However AA and AL showed no significant difference, which concurs with Takita et al (1992) Tsuda et al (1994), and Iida et al (1997) who in studies from Japan found no association between LOH at 16q 24 and lymph node metastasis. Although four studies are an insufficient number to draw any definite conclusions the possibility that the relationship between LOH at 16q and lymph node metastasis is different between high and low incidence populations deserves consideration and further investigation.

In all three study groups, at all ages, lymph node negative tumours had more LOH at p53 than node positive tumours; numbers were too small to allow statistical analysis. Sato et al (1990) and Nagai et al (1994) found an association between LOH on 17p and lymph node positive tumours, but both used the marker D17S5 which is distal to the p53 gene locus. Nagayama and Watatani (1993) however using a marker within the p53 locus found lymph node negative tumours to have more LOH than lymph node positive tumours, this finding is not inconsistent with my results.

Considering LN+ tumours only, AA had significantly more frequent LOH at 6q premenopausally than post menopausally ( $\chi^2$ =4.7, d.f.=1, p<0.05) where as AL and EL had more LOH in the older age groups but this was not significant. All LN+ tumours had more LOH at 16q in the older ages compared to the young, and this difference reached significance for AA ( $\chi^2$ =4.78, d.f.=1, p<0.05, pre/post menopausal,  $\chi^2$ =6.68, d.f.=1, p<0.01, under/over 44 years). It was LN+ tumours in the under 44 years of age

group however that showed the highest frequency of LOH at p53 in all the study groups.

#### Tumour size

No significant differences were found between LOH at 6q in tumours less than 2cm and those over 2cm, similar results were found by Iwase et al (1995) for LOH at ESR. In AA tumours over 2cm significantly more cases of LOH occurred in premenopausal patients than post menopausal ones, but the difference failed to reach statistical significance.

The cases from EL had significantly more LOH at 16q in tumours over 2cm ( $\chi^2$  =9.2, d.f.=1, p<0.005), with the same trend being seen in AL, although the numbers were too small to make an analysis. Younger patients in AA had more LOH in smaller tumours, but older patients exhibited significantly more LOH larger tumours (post menopausal  $\chi^2$ =5.4, d.f.=1, p<0.025, over 44 years  $\chi^2$ =8.4, d.f.=1, p<0.005). Several groups (Nagayama and Watatani, 1993; Tsuda et al, 1994; Hansen et al, 1998) found no association between LOH at 16q and but although all studied the region 16q24, the marker 16S413 was not assessed. Iida et al (1997) also failed to find an association, however although D16S413 was studied its results were pooled with other 16q markers for analysis.

LOH at p53 appeared to occur more frequently in larger tumours but differences with size were not significant which is consistent with the results described by Nagayama and Watatani (1993) and Nagai et al (1994). *Grade* 

Examination of LOH at 6q found significantly more in grade 3 tumours ( $\chi^2$  =5.2, d.f.=1, p>0.025) for EL cases, although AA and AL tended to have more LOH in grades 1 and 2. Noviello et al (1996) found no correlation with LOH at 6q and grade, however the loci studied, although in the same region, were not those used in this study. Iwase et al (1995) in a study of patients from Guy's hospital also found significantly more LOH at ESR in grade 3 tumours. Unfortunately, my data for LOH 6q is pooled from three loci, there being insufficient cases to consider individually, so a direct comparison with the results of Iwase cannot be made. However the markers studied include ones relating to the ER gene. There is a recognised association between loss of ER expression and grade (Maynard et al, 1978; Winstanley et al, 1991). Chappell et al (1997), in a selected group of predominantly grade 1 and grade 2 carcinomas did not find a relationship between LOH and ER status. Unfortunately, data was not available for ER status for all cases so a correlation was not possible. In

view of the differences between EL, AL, and AA it would be of value to compare ER status in the three ethnic groups.

At p53 AL and EL had a greater frequency of LOH in grade 1 and 2 tumours whereas AA had a higher percentage in grade 3. However, due to the low informativity rate there were too few cases to allow an accurate statistical analysis. The findings for AA varied with age, since the younger age groups had more LOH in grades 1 and 2.

Results from previous studies have varied possibly reflecting tumour heterogeneity. Niederacher et al (1997) described a positive correlation between LOH at p53 and high grade whereas Schmutzler et al (1997), failed to find this correlation. Schmutzler et al (1997) however did report an association between LOH at loci distal to p53 and high grade, but Varley et al (1991) analysing LOH the same region failed to find a correlation with grade.

Recent publications (Hansen et al, 1998; Roylance et al, 1999) have described an association between LOH at 16q and low histological grade, although others in earlier studies have failed to show this relationship (Tsuda et al, 1994). My study also failed to find a relationship between LOH at 16q and low grade, except in the younger age groups of EL. When all age groups were combined there was no significant difference in LOH with respect to grade (grades 1 and 2 compared to grade 3). Generally AA and AL had more LOH in grade 3 cases, and this was also seen in the older cases of EL. Several factors may contribute to the apparent inconsistency in results. These include:

a. the classification of high and low grade. Some studies compared only grade 1 with grade3 (Roylance et al, 1999), others grade 1 with grades 2 and 3 (Hansen et al, 1998), whereas I, due to the low number of grade 1 cases, compared grade 1 and 2 to grade 3.

b.the markers analysed on 16q vary

c.results from CGH studies represent a relatively large region on the chromosome not restricted to a single marker.

d. tumour heterogeneity can not be excluded, and to examine this extensive microdissection of individual tumours would be required.

The occurrence of LOH at 6q, 16q, and 17p in DCIS is indicative of their involvement in early stages of tumourigenesis in breast carcinoma (Fujii et al, 1996;

Munn et

al, 1996; Chappell et al, 1997; Buerger et al, 1999). Chappell et al (1997) found no association between LOH at 6q and differentiation in DCIS, and Fujii et al (1996) failed to find any at p53, or 16q. However Buerger et al (1999) did find an association between losses at 16q at well differentiated DCIS, and suggested that such losses might represent a sub type of DCIS. The fact that Buerger et al (1999) used CGH, which analyses all sites rather than selected loci, may account for the variation in results.

#### 4.6.4 Conclusion

In view of the number of cases, and those which are informative for LOH analysis, comparisons between AA and EL are more reliable than for AL. However, the findings indicate possible differences at the molecular level between ethnic groups and possibly even greater differences in relation to age.

In general there was a higher frequency of total LOH at the selected markers for EL cases. Interestingly these carcinomas had a lower frequency of large tumour size, nodal metastasis, and high tumour grade.

Correlation of LOH with the selected clinico-pathological features showed differences between the markers and the different ethnic groups.

For 6q there was a higher frequency of LOH in the older age groups for EL and AL, but premenopausally for AA. LOH at D6S186 appeared to be independant of age or ethnic group. The differences observed between AA and EL in LOH with respect to age appearing to be mainly attributable to differences in LOH at ERTA and D6S193 loci. There was no relationship with node status, no difference with size, more LOH in grade 3 EL tumours but more LOH in grade 1 and 2 in AA and AL cancer. Premenopausal cases in AA also showed significantly more LOH when either LN positive, or grade three tumours were considered whereas EL had more LOH in post menopausal cases. The difference in EL between pre and post menopausal patients however was not statistically significant. These observations illustrate the complexities and points to possible differences between EL and AA in relation to alterations on 6q. Some of this apparent complexity may be due to the fact that data was, in part, pooled from three markers, a study with a larger number of patients would enable each of the markers to be considered individually for all three study groups.

Differences also existed between EL and AA for 16q and 17p. There is a higher frequency of LOH at 16q in the older age groups of EL and AL; differences in LOH at 16q in node positive cases for EL but not AA and AL. However, for 16q age seemed important as well, since only premenopausal EL cancers had an association between LOH and grade, whereas LOH was more frequent in grade 3 cancers for AA, AL and

post menopausal EL. LOH was more frequent in tumours over 2 cms for EL, AL and postmenopausal AA but for premenopausal AA it was related to small size.

LOH at p53 in AA and EL occured in a higher frequency in all younger age groups, particularly in the under 44 years of age. This is of interest in view of the recent evidence of an increased incidence of p53 alterations in familial breast cancer due to changes in BRCA1 and BRCA2, and the interplay of these three genes in DNA repair (Marmorstein et al, 1998; Patel et al, 1998; Gonzalez et al, 1999; Venkitaraman, 2000; Welcsh et al, 2000). In addition LOH at p53, BRCA1 and BRCA2 has also been correlated to ER-ve tumours (Schmutzler et al, 1997).

Therefore, potential differences exist at a molecular level both in respect to ethnic origin and age. Larger studies are required, with other markers such as BRCA1 and BRCA2, to test the robustness of the findings and to elucidate inter-relationships further.

# CHAPTER FIVE

**CONCLUSION** 

#### **5.1 PROJECT OVERVIEW**

#### 5.1.1 Summary of results

A statistically significant difference was demonstrated in chapter two in the age of onset of breast cancer between those populations with the highest and lowest incidence. The association between ethnic origin and level of incidence was also found to be statistically significant, with the countries with lowest incidence coming from Africa and Asia and those with the highest incidence from the Mediterranean and Europe. This distribution appears not to have changed noticeably over a 20 year period.

The Western Region of Saudi Arabia (AA) and Leicester Asians (AL) were both found to have a younger average age of onset when compared to the Leicester European (EL) population. Use of ASIR and calculation of relative risk allowed the comparison of populations with different age structures over different age ranges. The ASIR for AA appears to be typical of that demonstrated for other low incidence countries with a small excess of very young cases, but a lower overall incidence especially in the age range 30-65 years when compared to EL. ASIR for AA was statistically different from EL in both younger and older age groups, and statistically different from AL in the older age group (45-69 years) but not in the younger age group (20-44 years). ASIR for AL was statistically different from EL in the younger age group but not in the older group.

Chapter three studied variation in selected clinico-biological markers with respect to ethnic origin and age. The function of these parameters was to act as surrogate markers of tumour behaviour. Differences were found between AA, AL and EL, with those between AA and EL frequently reaching a level of statistical significance. However it was not possible to describe either AA or EL as having a more aggressive profile. AA showed more aggressive clinico-pathological characteristics, but had the least aggressive characteristics when nuclear morphometry was considered. The converse was true for EL, which had a more aggressive nuclear morphometric profile, but less aggressive clinico-pathological characteristics. VMI showed no significant difference between any of the groups, the recorded rank order does not follow the pattern seen for nuclear morphometric measurements and for clinico-pathological measurements. Except for VMI AL had an intermediate rank order between AA and EL, with AL tending to be closer to AA in the younger age groups and to EL in the older age groups. AA and EL both possessing different aggressive characteristics may go some way to explaining the findings of some studies (Gillett et al, 1997; Ibrahim et al, 1998; Ezzat et al, 1999; Merchant et al, 1999) that despite worse clinico-pathological characteristics patients with young onset sporadic breast

cancer and those from low breast cancer incidence populations do not have a worse survival rate than older patients and those from high incidence populations. A proposition which is supported by observations by Baak et al (1992), that when comparing different populations morphometric characteristics and 10 year survival may be independent of clinico-pathological characteristics.

Data from chapter three also revealed a greater degree of homogeneity in AA compared to EL for all characteristics studied except tumour size. These observations provide support for the proposition that there are two types of breast cancer, and that AA consists predominantly of " young type" breast cancer, without significant numbers of "old type" breast cancer, the presence of which would otherwise add variation and increase the overall incidence.

The molecular markers examined in Chapter Four also exhibited differences between AA, AL and EL. If just AA and EL are considered, since AL numbers were generally small, in relation to the frequency of LOH in older and younger age groups, the following patterns were observed:

• LOH at three of the markers appeared to be related to age rather than ethnic group. AA and EL both exhibited more LOH in the younger age groups for markers D6S193 and p53, and more LOH in the older groups at the marker D16S413.

- LOH at ERTA showed differences between AA and EL (AL for both these was the same as EL). AA showed more LOH at ERTA in the young age groups, whereas EL showed more in the older groups.
- LOH at D6S186 appeared to be independent of age and ethnic group in the populations studied.

The results presented support the proposition made by Manton and Stallard (1992) that genetic factors are important in the aetiology of young breast cancer. With reference to the clinico-pathological characteristics of tumours seen in the AA study group, BRCA2 is a possible candidate gene in this population; however the lack of male breast cancer (Stratton et al, 1994) and young prostate cancer (Gayther et al, 2000) does not support this. Similarly no evidence of multiple incidence of breast and/or ovarian cancer makes BRCA1 an unlikely candidate, as is the recently proposed BRCAx gene(s) (Borg et al, 2000; Stratton, 2000) because of lack of an associated low grade in the series studied.

#### 5.1.2 Fulfilment of aims

The results presented support the hypothesis that breast cancer occurring in

different ethnic groups differs in respect to the age of onset and age specific pattern of incidence.

The Western Region population and Leicester Asian population when compared to the Leicester Europeans were found to have a more aggressive profile with respect to clinico pathological markers, but a less aggressive nuclear morphometry. There was no significant difference in VMI.

A PCR based, non-isotopic protocol was set up to examine molecular differences with respect to age and ethnic group.

At a molecular level differences were found to exist both in relation to age and ethnicity, the nature of the differences varying from marker to marker. There was no significant difference in total extent of LOH between the study groups.

#### 5.1.3 Ethical validity

Although appropriate ethical procedure has been used throughout this study, with regards to getting permission and protecting patient confidentiality, even the use of ethnicity to stratify patients has been criticised as being potentially unethical. Bhopal (1997) condemns much of the research comparing ethnic groups as "black box" epidemiology, which frequently only comes to the conclusion that a difference exists. Within this context my study has shown not only that differences exist between AL and EL but also that there are similarities between AA and AL, and has attempted to analyse these with respect to age, and to investigate them at a molecular level. In addition results are related to international variation in age of onset, overall incidence, and ASIR.

For a study to be epidemiologically sound Bhopal (1997) suggested:

- Care must be taken to compare like with like: Within this project the majority of all three study populations are urban dwellers with access to comparable medical care. The population size of the study regions is also comparable (Leicestershire having approximately the same population as Jeddah).
- Ethnic groups must be carefully defined: I chose the use of family name to differentiate between Asian and European patients. This approach has been used in earlier studies (Nicoll et al, 1986; Harland et al, 1997; Winter et al, 1999) and is particularly suitable where there is still limited inter marriage.

#### **5.2 PRACTICAL IMPLICATIONS**

Accepting sporadic breast cancer as an important disease in the young brings practical implications:

#### 5.2.1 Education

Awareness of breast cancer and that it not only is a disease of the old, together with knowledge of breast self examination, should be cultivated in the general population. This is especially important in those populations that appear to be predisposed to early onset breast cancer. Unfortunately it is many of these populations, including the Middle East and Asia, where traditional values make it difficult to discuss and demonstrate publicly subjects such as breast self examination. However it is encouraging that in Saudi Arabia now, as well as doctors explaining the procedure to patients on an individual basis, secondary school students are also being given lectures and demonstrations on the subject.

Reminding primary health care clinicians, especially those in the West where the majority of the breast cancer patients would be European and post menopausal, to be vigilant to the possibility of breast cancer in both the younger patient and in patients from ethnic minorities.

Related to breast cancer awareness is the need for regular mammographic screening. Some have reported that uptake of screening among ethnic minorities in the West is less than that in the European populations (Botha et al, 1993; McCarthy et al, 1998; Hedeen et al, 1999). Efforts should be made to ensure that all sections of the community are aware of the benefits of screening and are encouraged to utilise the facility.

#### 5.2.2 Mammographic screening

Tumours can be detected by mammography even before they are palpable and detection of smaller tumours often allows less radical surgery and improved survival (section. 1.4.1). Many have advocated aggressive screening at a young age (McCarthy et al, 1998; El-Tamer et al, 1999) especially for African and Asian patients.

Rosenquist and Lindfors (1998) investigated several screening protocols including screening all women 40 -79 years annually and all were found to be cost effective. Although mammographic screening has been criticised as having a very low degree of sensitivity under the age of 50 years (Peer et al, 1996), advances in accurately imaging the younger breast are being made. Lee et al (1999) proposed the use of MR imaging in the evaluation of problematic mammograms and Okamoto et al (1996) and Kossoff (2000) ultrasonographpy in the initial investigation of young breasts.

On balance I agree with Gail and Rimer (1998) that screening of women should be considered from the age of forty, at least in individuals and communities at higher risk for early onset breast cancer from the age of forty years. Tabar et al (1999) state that screening interval in women 40-49 years of 12-18 months would achieve a similar reduction in mortality as that seen in post menopausal women. Saudi Arabia, with its high proportion of premenopausal breast cancer would probably be a candidate for such a protocol.

#### 5.2.3 Diet

Though it is still not entirely clear what the exact role of diet is in preventing breast cancer, consensus would appear to advocate a reduction of intake of red meat, animal fats, and alcohol, and probably more importantly an increase in fruit and vegetables (and other sources of phyto oestrogens) (Stephens, 1997). Diet may prove to be only a confounding factor or it may not have the same effect on all populations but modifications such as these would be in any case generally advantageous to health.

#### **5.3 FUTURE WORK**

If the breast cancer patients in the Western region consist of, as proposed by this thesis, a relatively homogenous population of young type breast cancer then results of research on this population may be applicable to the minority young type breast cancer populations seen in the UK and other high incidence countries. Possibilities for future work could include:

- A larger scale investigation of the differences described between the cases
  presented in this project. Use of more cases would allow a more detailed analysis
  and would help eliminate any findings which were in fact artifactual due to low
  numbers. This would be particularly applicable to the Leicester Asian population.
- Inclusion of more markers, including those associated with metastatic behaviour e.g. 7q31 and 8p (Bieche et al, 1992; Yaremko et al, 1996; Yokota et al, 1999). Other possible choices of loci to be investigated would be BRCA1 and BRCA2. Both have been described as being associated with distinctive phenotypes in familial breast cancer (Breast Cancer Linkage Consortium, 1997) and it would be of interest to see if LOH at either of these sites correlated to differences described in the populations studied in this thesis. A more speculative choice would be that of the Cowden locus 10q 22-23 (Liaw et al, 1997; Marsh et al, 1997; Singh et al, 1998) associated with both increased risk of breast cancer and thyroid cancer. Both breast cancer and thyroid cancer exhibit a high relative risk in both the Saudi and British Asian populations, neither of which can be readily attributed to infective agents (unlike lymphoma which is also common in both populations and where infective agents may have a role in the aetiology).

225

- More detailed investigations of the loci studied in this project including possibly the expression of cell adhesion proteins and ER receptor status using immuno histochemistry. Cell adhesion proteins are of interest because the AA population appears to be more poorly differentiated (high cellularity values, and high grade) and have a greater ability to metastasise (higher percentage of lymph node positive cases) which indicates a possible alteration in cell:cell and cell:stromal interactions.
- Lawson et al (1999) suggested that low ER expression in normal Japanese breast is directly related to the low incidence of breast cancer in that country. It would be interesting to see if the same differences could be detected here, and also to compare ER expression in tumour samples.
- P53 could also be profitably investigated by comparing allelotypes as outlined by Sjalander et al (1996), and Weston et al (1997) both of whom described ethnic differences. Weston et al (1997) also found pre menopausal / post menopausal differences within their Caucasian study group.
- The relatively high incidence of tumours under 30 years appears to be a feature of populations which otherwise have a low incidence of breast cancer; a larger study would allow these cases to be considered as a sub group. It would be of interest to compare features of this sub group in the three study populations. A long term prospective study would allow a more detailed evaluation of possible family history in this sub group. None of the 51 cases under 30 years of age in AA were reported as having a family history, but it possible that this may have been been denied (or not revealed) by the patient for social reasons. Careful interviewing, together with genetic counselling if required, should help avoid this potential source of error.

#### **5.4 SUMMARY**

In brief, data presented in this thesis adds to the weight of evidence that there are ethnic and age differences in the incidence and presentation of sporadic breast cancer and that these differences are probably best explained by a two disease model of breast cancer of the type suggested by DeWaard and Manton and Stallard. Accepting this to be correct I suggest that it is possible that the pattern of breast cancer seen in the Western Region of Saudi Arabia is due not to an excess of young breast cancer (except possibly in the under 44 years) but a relative absence of the older type of breast cancer. Studying breast cancer in Saudi Arabia, and other low incidence countries may give information which can also be applied to young breast cancer world wide.
