ACKNOWLEDGEMENTS

ABSTRACT

Measurements of the work function, quantum yield and

low energy (6.0 eV < hV < 21.2 eV) photoelectron spectra are

presented for the simple metals In, Al, Pb and Sn in the liquid

and frozen solid states, and for Hg and the mercury alloys

$Hg_{.50}$- $In_{.50}$, $Hg_{.75}$-$In_{.25}$, $Hg_{.96}$- $Na_{.04}$ in the liquid states only.

The results obtained for the solid simple metals are consistent

with other published results. The results for the liquid are

very similar to those for the solid and are constant over a

broad temperature range above the melting point.

A Monte Carlo simulation of the photoemission process,

based on the 3-step model of Berglund and Spicer, has been

developed and used to examine the effects of variation of the

electron-phonon scattering length on the quantum yield and escape

depth of the photoelectrons. This programme has been used in

conjunction with an analytical programme, based on the work of

Krolikowski, to derive optical density of valence states functions

and electron-electron scattering lengths for the liquids.

In all cases the optical density of states functions show

much stronger structure than expected on the basis of a weak

scattering description of the liquid system and agree better with

theoretical predictions for the solid, indicating that some aspects

of the solid state band structure persist on melting. No

evidence for conservation of the momentum vector $\underline{k}$ or for non

constant matrix elements is observed.

In the case of mercury and the mercury alloys the results

obtained agree well with the pseudogap concept proposed by Mott.

CHAPTER 1:—   INTRODUCTION

   1.1.   Outline

During the past fifteen years there has been increasing

interest in the properties of liquid metals and alloys. This

has arisen naturally as earlier studies of the crystalline phase

have been extended into disordered systems. The liquid system

is attractive both to the theoretician and the experimentalist

as it is spatially isotropic and, unlike the amorphous solid,

offers a degree of disorder that may be easily reproduced.

There are, however, considerable difficulties in this

field — for the experimentalist there are the problems of the

high temperatures required (resulting in high vapour pressures)

and the corrosive nature of liquid metals, whilst for the

theoretician there is the problem of treating a disordered system

where long range translational order does not exist — precluding

the use of Bloch's theorem to simplify matters. This is

particularly true with the tight binding systems existing in

transition metals.

The work in the field to date has been summarised in

three major conferences (Brookhaven 1966, Tokyo 1972 and Bristol

1976) and in several reviews — notably those of Cusack (1972),

March (1969), Enderby (1972),and Faber (1972). From these it

is apparent that there is relatively little experimental data

available on the electronic structure away from the Fermi level,

although other aspects (such as the electron transport properties)

have been extensively studied and are relatively well understood.

This thesis describes a series of photoemission

experiments carried out on five liquid metals — aluminium, indium,

tin, lead and mercury and some mercury alloys. The object of these experiments was to obtain information on the valence band structure of these metals from measurements of their photoemission properties - notably the work function, quantum yield (as a function of photon energy) and photoelectron energy distribution spectra (E.D.C's). A computer model of the photoemission process was developed and used to examine the effects of scattering processes. This model was also used in conjunction with the experimental data to obtain values for the electron mean free paths and an optical density of states which could be compared both with theoretical predictions and the results of other workers.

1.2. Liquid Simple Metals

The metals chosen for this work, with the exception of mercury, are what are normally referred to as 'simple' metals, i.e. metals of high conductivity that do not possess a d or f resonance close to the Fermi level - this excludes transition, noble and rare earth metals and the chalcogenides.

Up to the present it has normally been considered that liquid simple metals could be adequately described in terms of a nearly-free-electron (n.f.e.) model where the disorder has largely reduced the scattering potential. There has been considerable work done in obtaining values for the structure factor $S(Q)$ (defined in the usual way as the expectation value of $Na(Q)a^*(Q)$ where:

$$a(Q) = \sum_i \exp(-i Q \cdot r_i) \qquad (1.1)$$

and N = number of scatterers, Q is a wave number and r_i refers to the positions of the nuclei) from X-ray or neutron scattering

experiments and, with the exception of small effects in non-cubic metals such as zinc and cadmium, the results agree well with a simple pairwise interaction between ions. By plotting structure factors against hard sphere diameter, Ashcroft and Leckner (1966) have obtained a universal curve which is in reasonable agreement with the hard sphere solution of the Percus—Yevick equation. However, in the case of the chalcogenides there is some deviation from this model and these must be considered in terms of non—central forces (Enderby and Hawker 1974).

Figure 1.1. shows the structure factor for lead, which is typical of a hard sphere—like metal - a strong first peak followed by oscillations which damp out in a few multiples of Q. As may be seen from Table 1.2., the electrons at the Fermi level in a simple metal such as sodium traverse many of the local arrangements between scattering events, which would be expected to cause considerable smearing of the E—k curve as suggested by Edwards (1962). This again contrasts sharply with the chalcogenides, such as tellurium, where the mean free path is only a few times the atomic diameter, with resultant strong local scattering. As will be discussed later, measurements of the optical properties also support this n.f.e. picture, showing little evidence of band structure.

1.3. Electron States in Disordered Systems — Theoretical

There are several different methods that have been used to obtain numerical results for simple liquid metals (a full review of these is given by Cusack 1972), but the majority

Fig.1.2 – Some basic physical parameters of some simple metals

of results have been obtained using a Greens function method
which was introduced by Edwards (1966). This has been used
as a basis for two different approaches.

The form of approach used by Chan and Ballentine (1972)
and Itami and Shijomi (1972) to obtain results for sodium,
aluminium, bismuth, mercury, indium and some alloys defines the
resolvant operator in the form:

$$G(E) = (E - H)^{-1} = \sum_n \frac{|\psi \rangle \langle \psi|}{E - E_n} \qquad (1.2.)$$

where $H = p^2/2m + V$ is the Hamiltonian and $|\psi \rangle$ and E_n are its
eigenvectors and eigenvalues.

This results in a density of states (per unit energy,
per unit vol., for a single spin orientation) of the form:

$$n(E) = L^{-3} \sum_k s(k,E) = (2\pi)^{-3} \int s(k,E) \, d^3k \qquad (1.3.)$$

where the spectral function $s(k,E)$ is defined as:

$$s(k,E) = \frac{-1}{\pi} \text{Im} \, G(k,E + i0) \qquad (1.4.)$$

where $G(k,E)$ is the ensemble average Greens function.

Figure 1.3. shows typical results for this method which
generally yields a free electron like $n(E)$, lead and bismuth
being the metals which show the greatest deviation from this.

Because of the lengthy numerical calculation involved
in this method, a simplified version has been used by Shaw and
Smith (1969) and Schneider and Stoll (1967) to obtain results
for nickel, potassium, lead, bismuth, indium and cadmium. In
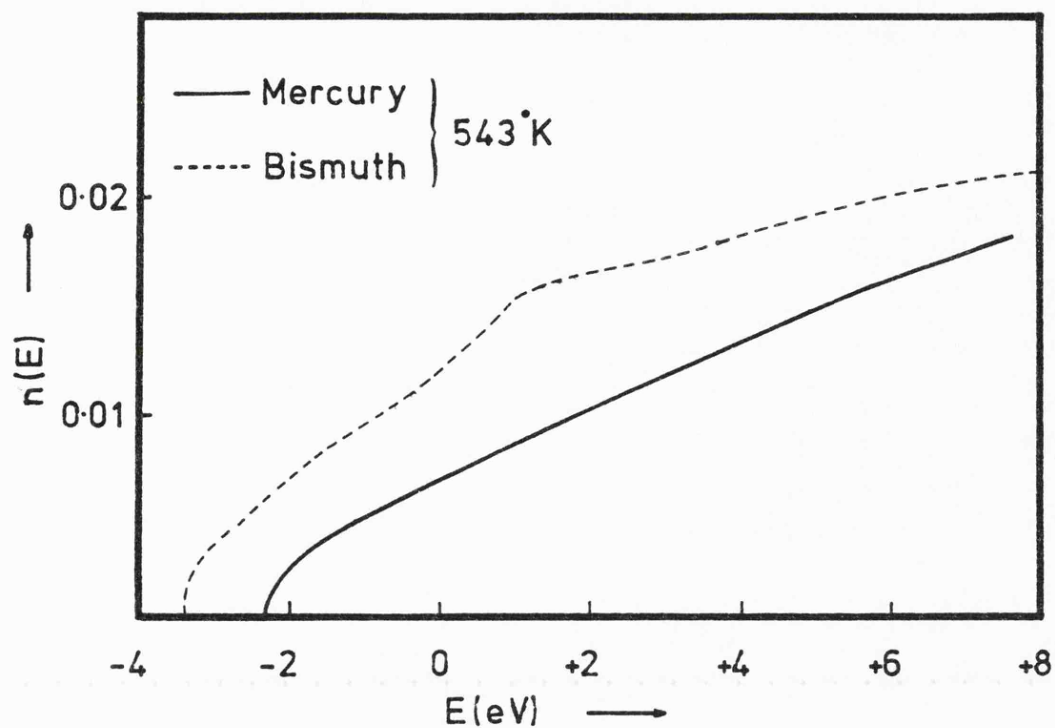

Fig.1.3 - Density of states for liquid mercury and liquid bismuth from Itami and Shijomi (1972)
Fig.1.4 - Density of states for liquid and solid indium from Shaw and Smith (1969)

this method the formal perturbation expansion for an energy

eigenvalue is written as:

$$E = \frac{k^2}{2m} + \langle k|V|k \rangle + \sum_{k' \neq k} \frac{\langle k|V|k' \rangle \langle k'|V|k \rangle}{E - (k')^2/2m} + \cdots \cdots , \quad (1.5.)$$

By taking the ensemble average and assuming a uniform

distribution of states in k space, the following relation for

n(E) is obtained:

$$n(E) = \frac{k^2}{2\pi^2} \left[\frac{\partial E(k)}{\partial k} \right]^{-1} \quad (1.6.)$$

Figure 1.4. shows typical results for this method.

This method ignores triplet correlations - the structure

that exists from the third term of the expression involving S(q),

the 2-body structure factors.

The relationship between these methods has been examined

by Ballantine and Chan (1972). They have shown that the second

method has given an exaggerated value for the pseudogap (the dip

in n(E) at the Fermi level) in mercury, implying that this

method is only reliable where the solid state density of states

is free electron like.

A third method, that of the Bloch density matrix, has

been used by Rousseau et al (1970) to obtain results for

beryllium. This method shows appreciable deviation from free

electron behaviour, whilst the first two methods show very free

electron like behaviour, as may be seen in the diagrams, where

the functions associated with crystallinity are washed out and

there is only a weak indication of a band gap.

More recently, interest has focussed on the use of a

tight binding method.   A discussion of this method and the

muffin tin potential which forms the basis of the Ziman—Lloyd

formalism is given by Watabe (1977).

1.4.   Electron States in Disordered Systems —
Experimental

There are several different techniques which have been

used to try to gain information on the electronic density of

states at or below the Fermi level.   Some of these are discussed

here.

1.4.1.   The Knight Shift (K)

This is a nuclear magnetic resonance (N.M.R.) technique,

the shift (K) being the fractional change in the N.M.R. magnetic

when the nuclei form part of a metal, relative to the field for an isolated

field \   This gives information on any departure from   atom.

$\searrow$ of $N(E_F)$

the free electron value and on any variation during melting.

Results to date show little effect on $N(E)$ on melting except in

cadmium (Seymour and Styles 1964), gallium and bismuth (Knight et

al 1959).   This failure to observe a change in K on melting is

not in agreement with the free electron picture.   However there

are masking effects due to electron—electron interactions, and

the observational accuracy is limited.

1.4.2.   Positron Annihilation

This technique enables information on the momentum

distribution of the electron to be gained by measurements of

photon angular correlation from the annihilation of high energy

(several MeV) positrons in the material.   Unfortunately the

interpretation of results is difficult as there is considerable

smearing of the angular correlation curve in liquid metals (West et al

1967) which considerably limits the usefulness of the technique.

1.4.3. Electron Transport Properties

A considerable amount of information on liquid metals

has been gained from measurements of the electron transport

properties, i.e. Conductivity (ρ), Thermopower (Q) and Hall

coefficient (R). Using a semiclassical nearly-free-electron

approach, where the electrons are described in terms of the plane

wave scattering of weak pseudo-potentials, Ziman (1961) has obtained

the following expressions for conductivity and thermopower:

$$\frac{1}{\rho} = \frac{3\pi\Omega}{\hbar\, e^2 v_F^2} \int_0^{2k_F} S(k)\,|v(k)|^2 k^3\, dk \qquad (1.7.)$$

$$Q = \frac{\pi k_B T}{3 e\, k_F}\; 3 - \left\{ \frac{S(2k_F)|v(2k_F)|^2}{\langle |v|^2 S\rangle} - \frac{\langle k_F(\partial|v|/\partial k)S\rangle}{\langle |v|^2 S\rangle} \right\} \qquad (1.8.)$$

where Ω is the atomic volume and k_F is the Fermi wavevector.

This approach has been discussed fully in several articles

(see Faber 1972) and although doubts have been cast on its

validity, mainly due to its dependance on the Born approximation,

it has been quite successful to date. The values of ρ obtained

for the alkali metals are in good agreement with experiment, and in

the case of divalent metals it has shown clearly why they have

lower values. The theory has also been successful in relating

the temperature dependance of ρ to the temperature variation of

S(q) but was initially unsuccessful in accounting for the

experimental values for mercury. More recently the pseudopotential

has been modified by Evans (1969) to overcome this problem.

In the case of the Hall effect the n.f.e. theory gives

the result:

$$R_H = \frac{1}{nec} \qquad (1.9.)$$

where

R_H is the Hall coefficient and n is the number of carriers/cm^3.

This expression is in good agreement with the observed results for most materials. It fails in the case of lead, but this could be due to the strong scattering in this material.

However, more recently Edwards (1966) has cast doubt on this n.f.e. explanation and has shown that the simple transport properties are not sensitive to small variations in the density of states.

1.4.4.   Optical and Spectroscopic Methods

The results obtained from low energy studies (e.g. Hodgson et al 1962) have provided some of the strongest evidence for the acceptance of the n.f.e. approach.

Almost all the results obtained are consistent with the classical Drude model which yields the expression for the conductivity:

$$\rho(\omega) = \frac{ne^2\tau}{m(1 + \omega^2\tau^2)} \qquad (1.10.)$$

where τ is the relaxation time.

One of the most notable results is that for aluminium, where the interband transitions are observed to disappear on melting, again in keeping with the predictions of the n.f.e. theory. The agreement is not good in the case of mercury, but there has been some dispute over the properties of this metal.

Schultz (1957) obtained results that were in good

agreement with the Drude model but later workers such as Hodgson

(1959) claimed to have measured values for ε_1 and ε_2 significantly

greater than those suggested by the theory.

1.4.5. Emission Spectrum Methods

With the development of ultra high vacuum apparatus

making it possible to obtain and maintain atomically clean

surfaces, the emission spectrum techniques such as ultraviolet

photoemission spectroscopy and X-ray photoelectron spectroscopy

have come into prominence. These techniques allow the density

of states away from the Fermi level to be probed. Early

results on liquids (Koyama 1968 and Stevenson 1968) have been

quite striking and the whole n.f.e. approach has been cast into

doubt by the discovery that structure observed in the density of

states persists on melting. Although the interpretation of

results is complicated by the effects of electron-electron

scattering processes, this technique is one of the most valuable

tools for the investigation of electronic structure. Its

application to liquid metals is fairly recent, and further work

is urgently needed to clarify the initial results. This

technique will be fully discussed in later chapters.

1.5. Outline of Thesis

It will be clear from the preceding that there is very

little definite information on the density of states in liquid

metals. Despite the success of the Ziman model in explaining

electron transport data, and the work of Edwards, the failures

of the n.f.e. theory show that it cannot be considered to be

totally satisfactory. Whilst the technique of photoemission

spectroscopy provides a means of directly probing the density of states away from the Fermi level, the work to date has mostly been on solids and gases, and there is very little data available for liquids. Although there are considerable experimental difficulties, Figure 1.5. shows that the vapour pressures of aluminium, indium, tin and lead are low enough to make these problems soluble, and that even mercury can be handled with the use of a mercury diffusion pump. These metals provide a range of types from the free electron like aluminium to lead with its strong scattering and mercury with its possible pseudogap. Thus a series of experiments on these metals should provide valuable data on the validity of the n.f.e. approach for liquid metals.

CHAPTER 2:—   THE PHOTOEMISSION PROCESS

2.1.   Historical Background

The photoelectric effect has been known for some time, the
basic equation formulated by Einstein in 1905 being:

$$E = hV - \phi \qquad (2.1.)$$

where E = energy of the emitted electron, hV = photon energy and
ϕ = work function.

Figure 2.1. illustrates the basic process.   The electron
states in the valence band are filled from the bottom of the band
to the Fermi level.   Since a metal is being considered there is
no forbidden gap above this level, and empty states are continuous
to the vacuum level and beyond.   If a photon of energy hV
impinges on the metal and excites an electron of energy E, it
will raise the electron energy to $E + hV$.   If this increase
raises the electron above the vacuum level, it may then find its
way to the surface and be emitted, its energy outside the metal
now being $E' = (E + hV) - (E_f + \phi)$.   Since the initial energy E
may be anywhere in the valence band, E' may be
anywhere between $(hV - \phi)$ and zero.   The probability of an
electron being emitted with any particular energy E' is dependant
on the number of electrons with energy E — thus, if a large
number of photons is considered, the distribution of final energies
will be a reflection of the density of states, modified by some
function dependant on the internal scattering processes and the
escape probability at the surface.   This is the basis of the
technique of photoelectron spectroscopy.

The first attempt at photoelectron spectroscopy was made
by Richardson and Compton (1912).   Whilst they provided a useful
Fig. 2.1 - Basic photoemission process in a metal

illustration of the technique they also revealed its major

limitation — which is that, without an atomically clean surface,

the electrons are scattered so strongly at the metal-vacuum

interface that all information in the spectrum is completely

'washed-out'. Thus it is only in the past two decades, when

the advent of ultra high vacuum (U.H.V.) apparatus has made the

preparation of atomically clean surfaces possible, that the

technique has become viable.

However, theoretical advances were made. Fowler (1931),

by the use of Fermi-Dirac statistics, succeeded in explaining

theoretically the shape of the i-V curve near threshold (i.e.

$(hV - \phi)$ is very small). Assuming that (a) only electrons for

which $E > (\phi + E_f)$ at right angles to the surface may escape, and

(b) that all electrons satisfying (a) have equal probabilities

of escape, he obtained the expression:

$$Y \propto (hV - \phi)^2 \Big/ (E_f + \phi - hV)^{\frac{1}{2}}$$

for a given temperature T

(2.2.)

where Y = quantum yield. Thus, by plotting $Y^{\frac{1}{2}}$ vs hV, an

accurate value of ϕ may be obtained. This is called a Fowler

plot and is a very useful technique.

2.2. Present Theories

The current theories of photoemission fall into two main

groups, using either a general formalism or a model of the process.

2.2.1. Formalistic Theories

In these theories the generation, travel, scattering and

transmission of the photoelectron are treated as a single process

by means of first principle quantum mechanics. This has been
done by several workers (e.g. Mahan (1970), Schaich and Ashcroft
(1970), Caroli et al (1973)), using a variety of approaches.
Mahan has performed calculations using a scattering formalism
and Schaich and Ashcroft have considered the quadratic response
of the system to an applied electromagnetic field. These
theories include the effects of inelastic electron-electron
scattering but make no allowance for the effect of electron-ion
interaction, which in the case of a liquid metal may well be an
important effect. Whilst all these theories are satisfactory
from a theoretical point of view, they are highly complicated
and, in order to give an effective solution for a real case, it
is necessary to make assumptions and simplifications that are
not satisfactory.

Norris and Williams (1976) have reported calculations
for aluminium based on the theory of Schaich and Ashcroft.
Starting from the 'golden rule' expression for the time-averaged
photocurrent outside the metal as a summation over a continum
of the form:—

$$\langle J(r) \rangle = \frac{2\pi e}{\hbar} \sum_{m,u} n(E_m) |\langle m | \frac{i\hbar e}{mc} \underline{A} \cdot \nabla | u \rangle|^2 \delta(E_m + \hbar\omega - E_\mu) \quad (2.3.)$$

where $\langle m|$ is an initial one-electron state of the unperturbed
system with occupation $n(E_m)$ and $|u\rangle$ is a final state which has an
outgoing plane wave component at infinity in the vacuum. It is
also a decaying excited state in the presence of a boundary which
accounts for transmission and scattering. $\underline{A} = A\hat{\varepsilon}$ is the vector
potential. By then making suitable assumptions in the preceeding
equation, namely that $\hat{\varepsilon}$ is parallel to a near perfect surface,

and by factorising out transmission and scattering effects, they obtained the following expression for the energy distribution:—

$$N(E,\hbar\omega) = C\left\{\sum_{i,f} n(E_i)|\langle i|\underline{A}\cdot\nabla|f\rangle|^2 \delta(E_i + \hbar\omega - E_f)\delta(E_f - E)\right\}T(E) \quad (2.4.)$$

i, f being initial and final states of the perturbed system and T(E) being the probability of escape without scattering. This may be simplified further by assuming that, in a disordered system such as a liquid, the matrix elements which impose conservation of the momentum vector may be considered to be constant.

This reduces the above equation to:—

$$N(E,\hbar\omega) = C\rho(E - \hbar\omega)\rho(E)T(E) \quad (2.5.)$$

This does rely on gross simplification but gives a basis for the interpretation of photoemission spectra. Using equation 2.2. and ignoring final state scattering, Norris and Williams obtained EDC's for aluminium of the right general shape but lacking the structure that is observed experimentally.

2.2.2. Model Theories

The earliest effective model theory, and still the most useful, is that of Berglund and Spicer (1964), modelling the photoemission process as a series of 3 semi-classical steps as follows (see Figure 2.2.):—

1. The photon is incident upon a metal surface. It penetrates the surface (assuming the reflectivity is zero), is absorbed and generates a 'hot' or excited electron.

2. The electron travels towards the surface of the material, possibly undergoing some scattering process as it

Photon

VACUUM

METAL

3. Electron reaches the
surface & escapes

2. The electron "walks" through
the material, interacting with
phonons & other electrons

1. A photon enters the material & is
absorbed, generating a "hot" electron
Fig. 2.2 - The 3-step process

does so.

3. The electron reaches the surface and escapes.

Step (1) allows the possibility of two types of optical

transitions for the excitation of the electron.

a) Direct transitions: In a crystalline structure,

the crystal momentum must be conserved. This means that in a

band structure the transitions must be vertical, implying to

the photoelectron spectroscopist that the structure he observes

in the density of states should vary both in strength and position

relative to the Fermi edge as a function of the photon energy,

due to the coupling of the initial and final states by matrix

elements.

b) Non direct transitions: In this case it is

assumed, by presuming some unspecified many body interactions, that

crystal momentum need not be conserved. This means that there

is little effect from the matrix elements, which are usually

assumed to be constant, and hence that the structure observed

should be constant both in position and strength relative to

the Fermi edge.

Later workers have used both types of transitions in

discussing results for different metals (see for example Eastman

(1969), Shaw and Smith (1969)) however, as will be seen later,

the results obtained in this study are consistent with the non-

direct approach and this is considered in more detail in Chapter 3.

The model contains several assumptions which are listed

here (see also Eastman (1972)):

1) That the matrix elements are constant.

2) That the emission of electrons is purely a bulk process.

3)   That the distribution of the directions of the excited electrons is isotropic.

4)   That only inelastic electron-electron scattering is considered.

5)   That the probability of an electron-electron event may be defined in terms of a mean free path l_e.

6)   That the inelastic scattering is isotropic.

7)   That when the electron reaches the surface, its escape probability is assumed to be unity if its momentum normal to the surface is greater than some excited value, and zero if it is less.

These are a fairly drastic set of approximations and it is obvious that some of them are not well justified. However, this model has enjoyed a fair degree of success and, in view of the difficulties inherent in the formalistic theories, it will be adopted as the basis for the interpretation of the results obtained in this work. The model does need to be extended, since in a liquid metal the electron-ion scattering length is very short, which means that it is no longer possible to view the transmission of the electron only in terms of inelastic electron-electron scattering. Other scattering processes must also be taken into account.

2.3.   Scattering Processes

There are three major scattering processes which need to be considered for a liquid metal. These are electron-electron, electron-phonon (or electron-ion) and electron-plasmon interaction.

In a metal, electron-electron interaction represents the major source of energy loss for an excited electron. The excited

electron interacts with an electron in the valence band, transferring energy to it. This process (Figure 2.3.) involving the loss of energy E from the excited electron - ignoring $\underline{k}$ conservation - may be shown (Krolikowski 1969) to have a probability of occurence P of the form:-

$$P \propto \int_E^O N_v(E_b) \, N_c(E_a - E) \, dE_b \qquad (2.6.)$$

N(E) being the density of states at energy E, and E_a, E_b being the energies of primary and secondary electrons.

If this probability P is averaged over many events it can be shown (Stuart and Wooten 1964) that the average energy loss of the excited electron in one electron-electron collision is one-half of its energy in excess of the Fermi energy. It may thus be seen that in the case of say, excitation by 10 eV photons of a metal with a 4 eV work function energy, that the probability of the electron surviving more than two collisions and retaining sufficient energy to excape is small. Therefore the probability of electron-electron interaction is a limiting factor in the quantum yield of the material.

This probability of an electron-electron collision may be expressed in terms of a mean free path or scattering length, which is a function of the energy of the excited electron. A fairly simple treatment of the scattering (Krolikowski 1968) gives an energy dependance of the form $E^{-3/2}$, and if this is compared with more complex predictions (Quinn 1962) or with experimental data, (see Figure 2.4.) it may be seen to be a reasonable fit. Values of the mean free path in liquid metals are of the order of a few tens of angstroms at 10 eV above the

$E^{-\frac{1}{2}}$ matched to low energy
experimental results

Fermi level, rising to several hundreds of angstroms at lower

energies so that, in the example above, the mean free path will

typically vary in the range 10 - 100 $\overset{o}{A}$. The escape of electrons

that have undergone a single collision results in a large peak

in the energy distribution spectrum at low energies and in the

case of a dirty surface this peak is considerably enhanced,

often to the extent of completely blurring out all details in

the higher energy part of the spectrum. This possibly arises

because the mean free path at the surface is greatly reduced,

causing an increased number of collisions, whilst the nearness

of the surface still allows a high probability of escape for the

electron after collision. It is thus vital to obtain as clean

a surface as possible.

The second major scattering process is that of electron-

phonon interaction. In this, an excited electron interacts with

the lattice in the material and either gains or loses a small

amount of energy (of the order of 0.05 eV). As in the previous

process, the probability of an event may be expressed in terms of

a mean free path (1_p), but this is not significantly energy

dependant over the energy range used in this study. In the

case of a semiconductor with a tightly organised lattice, this

mean free path may be very long - of the order of several hundred

angstroms - but in a disordered system such as liquid metal it

can be as low as a few angstroms (Cusack 1963).

Since the energy exchange in this interaction is quite

small, and may equally well be a loss or a gain, the effect should

be not to produce a low energy peak, but rather to blur

the structure of the energy distribution spectrum, the amount of

blurring increasing as the mean free path decreases. The effect

on the quantum yield is not clear, and this is discussed in more
detail in Chapter 3.

The third major process is that of electron-plasmon
interaction. In this process the electron causes a plasma
oscillation - a longitudinal vibration of the conduction electron
gas - losing energy in the process. The plasmon has a definite
lifetime and a fixed frequency which may be measured by observing
electron energy loss spectra (Powell 1968). There are two types
of plasmon - surface and bulk - with different frequencies, the
surface effect involving motion of the conduction electrons to
a depth of 100 $\overset{o}{A}$. The decay of the plasmon causes a peak in
the quantum yield at the characteristic frequency, and this has
been observed in photoemission experiments on Al (Endriz and
Spicer 1974).

There is one other process which may affect the
photoelectron spectrum and the yield. This is the generation
of an Auger electron. The excitation of a photoelectron leaves
a 'hole', either in a core state or in the valence band, and an
electron from a higher state may then combine with this 'hole'
releasing energy for the excitation of another electron to above
the Fermi energy (see Figure 2.5.). In the case of ultraviolet
photoemission, the probability of generation of an electron with
sufficient energy to escape is fairly small and, as may be seen
from the results in Chapter 3, the contribution to the electron
energy spectrum is not significant.

In Chapter 3 it will be shown how these processes may
be modelled, and their effects on the final EDC and yield
determined.
Fig. 2.5 - Generation of an Auger electron

CHAPTER 3:—   COMPUTER SIMULATION OF THE
                     PHOTOEMISSION PROCESS

3.1.   Introduction

As stated in 2.2., although the complexity of formalistic

theories of photoemission tend to preclude their application to

real systems, the 3-step model of Berglund and Spicer has enjoyed

some success in the interpretation of photoemission results and

this has been used as the basis of analytical simulations (notably

by Krolikowski 1969) and for Monte Carlo type analyses (notably

Stuart and Wooten 1964 and Leckey 1972). However, these analyses

have been for solids and,when considering the transport of the

excited electrons to the surface, have only taken account of inelastic

electron-electron scattering mechanisms. In a solid with a well

defined crystal structure this is probably adequate, since the

scattering length for an electron-ion interaction is very much

larger than that for an electron-electron event, but in the case

of a liquid the electron-ion scattering length can be very short

(see Cusack 1963), and the effect of this mechanism on the

resulting photoelectron spectra and yield is not obvious. There

are of course other effects, such as the possibility of electron-

plasmon interaction and the Auger generation of photoelectrons

which may also influence the final spectra, and whose importance

is again not obvious.

In the absence of a satisfactory analytical expression

for the electron-ion scattering of electrons in a liquid metal,

and the relative importance of the various mechanisms being

unknown, it was decided to attempt a Monte Carlo simulation

rather than an analytical one.

In this chapter the structure of the Monte Carlo

programme is considered in detail. The results obtained for

a free electron like metal are compared with those of the

Krolikowski analytical approach, and the programme limitations

are discussed. The effect of variation of the parameters is

also discussed.

3.2.   The Monte Carlo Programme

The basis of a Monte Carlo simulation is that the fate

of each individual photon and electron is followed — each decision

about their fate being made by a random number generator, where

the random number distribution has been suitably biased to take

account of the relative probabilities of various events. As will

be fairly obvious, this technique uses a lot of computer time

since a very large number of photons and electrons must be

followed to reduce the statistical uncertainty involved to an

acceptable level. However, the technique does possess the

virtues of great flexibility, since it is only necessary to be

able to assign a probability to an event to be able to take

account of it.

In order to keep the required computer time down, it was

decided to make some simplifying assumptions in addition to those

normally made in the 3-step model (see 2.2.).

1. Any electron whose energy fell below that necessary

for escape over the surface barrier was considered to have no

chance of escape and was ignored from that point.

2. So that it was unnecessary to consider tertiary

electrons (i.e. secondaries created by secondaries), the

programme was confined to a maximum photon energy of 10.2 eV.

Stuart and Wooten (loc.cit.) have shown that an electron loses, on average, half of its energy in excess of the Fermi edge in each collision. So, as the work functions being considered are between 4 and 4.5 eV, it may be seen that this results in a very small probability of a tertiary electron being generated. After each electron—electron interaction, the electron with the higher final energy was considered to be the primary (the electrons being indistinguishable).

3. Since no evidence of direct transitions was observed in the spectra obtained from the liquid metals being studied, it was assumed that all transitions were non—direct.

4. Since none of the metals being considered are known to have a bulk plasmon in the energy range being considered, the effects of electron—plasmon interaction were neglected.

A full flow chart of the programme is shown in Figure 3.1. Let us now consider the steps in detail:—

3.2.1. The Photon Entry

Only absorbed photons are considered, and the incidence of the photons onto the surface is assumed to be normal. Allowance for reflection at the surface, and for refraction in the case of non—normal incidence, is trivial and it was not felt necessary to include this in the original programme. Non normal incidence will, of course, result in the generation of excited electrons closer to the metal surface — hence it should cause a significant change in the yield.

3.2.2. The Photon Walk

Fig.3·1 – Flow chart for Monte Carlo programme

penetrates the surface of a metal of an absorption coefficient $\alpha(\omega)$, then the resultant intensity at a point a distance x from the surface may be expressed in the form:-

$$I(x,\omega) = I_o(\omega) e^{-\alpha x} \qquad (3.1.)$$

If each photon absorbed then results in an excited electron, the number of excited electrons generated between x and x + dx will be of the form:-

$$G(x) \propto \alpha e^{-\alpha x} \qquad (3.2.)$$

i.e. the probability of a photon creating an electron at a given depth will vary according to the exponential of the depth. Thus if a_1 is a random number from a normalised distribution of random numbers, and x is selected according to the relationship:

$$x = -\alpha \ln(a_1) \qquad (3.3.)$$

then if the values of x selected are considered for a large number of photons, the resulting distribution will be as in (3.2).

A record of x is kept in the programme so that, at the end, the initial value of x for all the photoelectrons which escaped may be averaged to give a value for the effective probe depth at the photon energy under consideration.

3.2.3. Generation of the Photoelectrons

The photon which has penetrated a depth x into the

material is now absorbed by an electron of energy E. Two things

are immediately apparent - firstly, E must be such that

$E + \hbar\omega > E_f$ (or the exclusion principle will be violated);

secondly, that the probability of selecting a given E must vary

according to the number of electrons with that energy (i.e.

biased to higher values of the density of states $N_v(E)$).

It has been shown by Krolikowski (loc.cit.) that, for

constant matrix elements and non-direct transitions, the

fractional number of electrons excited from the valence band to

a conduction band state of energy E, $G(E)$, may be expressed

in the form:-

$$G(E) = \frac{N_c(E) N_v(E - \hbar\omega)}{\displaystyle\int_{E_f}^{E_f + \hbar\omega} N_c(E) N_v(E - \hbar\omega)\, dE} \qquad (3.4.)$$

Now, for a fixed ω this may be reduced to:-

$$G(E) \propto N_c(E) N_v(E - \hbar\omega) \qquad (3.5.)$$

Therefore, in order to work out the relative probabilities of

various transitions we must first work out this expression.

Unfortunately, this distribution cannot be described by some

simple relation so, instead of considering it analytically, it

is necessary to treat the distribution as a histogram of energy

interval ΔE. If the histogram is then integrated and normalised,

using a Simpsons rule integration, and a normalised random number

a_2 is selected, the probability of it falling between

$N_c(E)N_v(E - \hbar\omega)$ and $N_c(E + \Delta E)N_v(E + \Delta E - \hbar\omega)$ will be proportional to the area of that segment of the histogram i.e.

$$N_c(E)N_v(E - \hbar\omega)\Delta E \qquad\qquad (3.6.)$$

since ΔE is a constant, this will achieve the desired effect of biasing the energy selection towards higher values of the density of states. However, in practice this results in a problem since the computer must then make a search to determine between which points on the normalised histogram a_2 lies, which is very time consuming. It is thus necessary to take steps to remove the need for this search. This was done by taking a one-dimensional array X of 10,000 'slots'. Each element of this array was assigned a value of E, the number of elements with any particular value of E being proportional to the probability of selection of that E (i.e. $N_c(E)N_v(E - \hbar\omega)$ see Figure 3.2.). Thus in selecting a_2, the value of E assigned to $X[\text{int.}(a_2) \times 10,000]$ was chosen as the electron energy, achieving the necessary bias without the need for a search.

In practice, the selection was of course limited to those values of E allowed by the exclusion principle. This technique results in some quantization of the energy selection but, since $\Delta E = 0.1$ eV, this was not significant. A record was kept in the programme of the values of E selected, and this was printed out at the end to check the procedure.

The initial energy E having been selected, the excited energy E4 is thus $E + \hbar\omega$. If E4 < $E_f + \phi$, the electron is considered to be unable to escape and a new photon is then
Fig.3.2-Setting up of energy selection array

considered.

If the initial selection energy E is low enough, there is a possibility of the generation of an Auger electron. This will be considered in 3.2.6.

3.2.4. The Electron Walk

The energy of the excited electron having been decided, it is then necessary to decide how far the electron will travel and in what direction. Since we are dealing with a liquid metal, it is not unreasonable to assume that the material is isotropic and there is an equal probability of the electron travelling in any given direction. In this case the direction of travel may be defined simply in terms of one angle Θ, the angle to the normal to the surface. This assumption is not a limitation of the programme, as it would be simple to programme a bias into the distribution (as for the electron energies) if we were dealing with a crystal. However, if the value of is selected according to the expression:-

$$\cos(\Theta) = 2(a_3 - 1) \qquad (3.7.)$$

where a_3 = normalised random number

as derived by Stuart and Wooten (loc.cit.), it may be seen that this will yield an isotropic distribution.

The determination of the distance 'walked' is rather more difficult. We are concerned with two scattering processes, each with its own mean free path, of which one (l_e) is energy dependant. However, for any given l_e and l_p, it is possible

to define a total mean free path (l_t) in terms of the expression:-

$$\frac{1}{l_t} = \frac{1}{l_e} + \frac{1}{l_p} \qquad (3.8.)$$

As in the case of the photon walk, the probability of the electron travelling a distance l before a collision will vary exponentially, and thus the 'walk' length may be selected according to an expression similar to (2) to give the correct distribution, i.e.

$$l = -l_t \ln(a_4) \qquad (3.9.)$$

where a_4 = normalised random number.

For the purpose of this study it was decided to use the expression for l_e derived by Krolikowski (loc.cit.), i.e.

$$l_e(E) = L_o \frac{\sqrt{E}}{\int_{E_f}^{2E_f - E} d(E_v^o) \int_{(E_f - E_v^o)}^{\frac{1}{2}(E - E_v^o)} d(\Delta E) N_v(E - \Delta E) N_c(E_v^o + \Delta E)} \qquad (3.10)$$

where L_o is a normalisation constant fixing the value of l_e at a particular final energy E_o^o.

For a free electron material this may be approximated to the form:-

$$l_e(E) = L_o E^{-3/2} \qquad (3.11.)$$

and this was used in the programme.   Again, this is not a basic

limitation in the simulation - by definition of a suitable

one-dimensional array for l_e, any biasing could be achieved.

This form for l_e was simply used as a convenient starting point.

The length and direction of the electron walk having

been determined by the above means, it now remains to decide

whether the walk will bring the electron to the surface.   Since

the initial depth of generation (x_1) is known, the new distance

from the surface will now be:-

$$x = x_1 - l\cos\theta \qquad (3.12.)$$

If this is now negative (i.e. the electron has reached the

surface), the energy of the electron normal to the surface is

then calculated to see if the electron can escape, i.e.

$$E\cos\theta > \phi \qquad (3.13.)$$

If this is so, then the fact is recorded in the fate counters

along with the electron energy outside the material and its

angle of escape.   If not, then the electron is considered to

have been reflected (i.e. x becomes -x).

3.2.5.   The Collision Process

If the electron does not reach the surface, or is

reflected, the type of scattering event it undergoes must be

decided.   This may be done simply in terms of the mean free

path, since the probability of it undergoing an electron-electron

event may be expressed in the form:-

$$P \propto l_t / l_e \qquad (3.14.)$$

see Stuart and Wooten (loc.cit.).

Thus by choosing a normalised random number a_5, correct biasing will be given by the conditions:

if $a_5 > l_t/l_e$ the event is electron-electron

if $a_5 < l_t/l_e$ the event is electron-ion

3.2.5a   Electron-ion Events

The process is considered quite simply in terms of the electron either gaining or losing (with equal probability) a quantum of energy E_p. E_p is considered for the purpose of the simulation to be $\simeq 0.04$ eV, but for $E_p < 0.1$ eV the programme was not sensitive to the exact value. The sign of the energy exchange was determined by a normalised random number a_5 by the conditions:

$a_5 > 0.5$ E_p positive

$a_5 < 0.5$ E_p negative

3.2.5b   Electron-electron Events

This process is rather more complicated. The probability of an electron of energy E_1 interacting with an electron of energy E_2 with an associated energy exchange of ΔE may be expressed in the form:

$$P \; \alpha \int_{E_1 - E_2}^{0} N_c(E_1 - \Delta E) \; N_c(E_2 + \Delta E) \, d\Delta E \qquad (3.15.)$$

(Since the electrons are indistinguishable, an energy exchange of $\Delta E > (E_1 - E_2)/2$ need not be considered).

To take full account of this in deciding the value of E would be very difficult, since it would be necessary to work out the product $U(E) = N_c(E_1 - \Delta E) \, N_c(E_2 + \Delta E)$

for all possible values of E_1 which would require an impossible amount of storage space in the computer. However if $N_c(E)$ is considered to have a simple form, such as a free electron variation, it may be shown that the form of $U(E)$ does not vary significantly over a large range of E. Thus if $U(E)$ is worked out for the maximum value and put into an array (as for $N_v(E)$ $N_c(E + \hbar\omega))$,ΔE may be selected from this without introducing too much error. E_2 is then selected for the initial probability array, limiting the choices to $E_1 - E_2 > E_f - E$ to take account of the exclusion principle.

Thus E_2 and ΔE have been determined taking account of the necessary factors in the probability expression but in a form that is fairly simple to programme. The final energies will be $E_1 - \Delta E$ and $E_2 + \Delta E$, the higher energy always being considered to be that of the primary.

After the scattering event, the secondary is followed for one further walk to see if it escapes. If it does not, it is then neglected. The primary is followed until its energy is too small to allow it to escape.

3.2.6.   The Auger Process

When an electron is excited from below the Fermi level it leaves a hole with which an electron higher in the band may recombine with the release of some energy E^o. This energy may then excite another electron to above the Fermi energy (see Figure 2.5.). The energy of the electron which recombines with the hole may be selected using the previously set up probability array - disregarding those energies which are below the energy of the hole, i.e. the random number selection is limited to those

states permitted by energy considerations. This determines the

energy available for excitation of the second electron (if this

is less than $\emptyset$, the energy is too small to need to be considered).

Its energy may be selected from the same probability matrix,

having regard for the exclusion principle. The Auger electron

is then treated in the same manner as for a secondary electron

i.e. is followed for one walk, examined for boundary conditions

and then disregarded if it does not escape.

3.2.7. The Fate Counters

There are three sets of counters for the escaped

electrons - one for primaries, one for secondaries and one for

Auger electrons. For the purposes of these counters a primary

is considered as an electron that escapes without undergoing an

electron-electron collision. These are basically a series of

slots to which the electron is allocated according to its energy

and angle of escape.

When all the photons have been considered, these counters

may be interrogated to obtain the yield and an EDC (or separate

yields and EDC's for the individual angular sections).

3.3. Use of the Programme

As stated earlier, several of the necessary factors for

the programme will be known e.g. work function, photon energy,

Fermi energy and attenuation depth. The electron-ion interaction

energy is not known exactly but experiment shows that it is a

non-critical factor. The major unknowns will be l_e, l_p and

the form of the density of states. Values for l_e, l_p could be

estimated using a short version of the programme which did not

contain the fate counters, but only a totaliser for the yields

of primary, secondary and Auger electrons. This allowed several

values of l_e, l_p to be tried, since less photons are needed to

give a reasonably accurate yield compared with the number

required for an EDC (about 25,000 photons was found to be

adequate on a basis of reproducibility). Experiment showed

that the yield is not critically dependant on the density of

states, assuming it is basically free electron like. Thus

l_e, l_p may be modified to match the programme yield to the

experimental yield, and the density of states may then be

modified in the full programme to match the predicted EDC to

the experimental one.

3.4.   Results

3.4.1.   Free Electron Yield

As mentioned earlier, this programme and that of

Krolikowski are based on the same 3-step model. It thus follows

that, since the major difference in the two programmes is the

inclusion of electron-phonon scattering, for $l_p = \infty$ the two

should give identical results. Accordingly, both programmes

were run for a free electron density of states over a range of

photon energies, the results of which are shown in Figure 3.3.

It may be seen that the agreement is highly encouraging. The

values of α and l_e are fairly typical for a free-electron-like

material.

3.4.2.   Effects of Electron-phonon Interaction

The programme was run using a free electron density of

$L_e = 25\,\mathring{A}$ at $8.6\,eV$ above E_f
Fig. 3.3 - Predicted yield of a free-electron metal

states for a range of values of l_e and l_p to determine the effect

of electron-ion interaction. Figure 3.4. shows how the escape

depth (i.e. the average depth of generation of those photoelectrons

that escape) varies with l_p for a variety of values of l_e. It

may be seen that it is very strongly dependant upon both parameters,

though less dependant on l_p and only becoming seriously affected

by this when it is appreciably less than l_e. It does however

vary almost linearly with l_e.

Figure 3.5. shows the variation of the primary yield

with l_p for a range of values l_e. It is immediately apparent

that the yield is not strongly dependant on l_p but varies almost

linearly with l_e. A low value of l_p when l_e is large can

however cause an increase in the yield. On a simplistic basis

this may well be considered to be due to the low l_p causing an

increased probability of scattering the electron towards the

surface whilst the high l_e reduces the probability of a collision

that might result in a significant energy loss.

It is thus apparent that the major effect of a low l_p

is on the escape depth rather than the yield, and this indicates

that the Krolikowski programme should give adequate results

even for a liquid metal.

3.4.3.   Prediction of EDC's

As pointed out in 3.1., the major limitation of a

Monte Carlo process is that, in order to reduce the statistical

uncertainty in a result, a large number of events must be

considered, with a consequently long computing time. Figure

3.6. shows a predicted EDC (for a free electron density of states)
Fig.3.4-Var'n of escape depth with scattering lengths

Energy of initial state (eV) ⟶

Electrons /abs. photon/eV $\times\,10^3$ ⟵
Fig. 3.6 - Predicted EDC for a free-electron metal

from the Monte Carlo programme compared with the equivalent

Krolikowski EDC.   It may be seen that, whilst the general

agreement in shape is good, there is a large amount of scatter

in the points obtained using the Monte Carlo approach.   This

could be reduced by increasing the number of photons considered,

but it was found that in order to reduce the scatter to an

acceptable degree it was necessary to consider of the order of

10,000,000 photons, resulting in the use of an impracticable

amount of computer time.

3.5.   Interpretation of Results

Whilst this programme was under development, work was

also undertaken by Dr. J. Bethel and Dr. S. Holloway of the

University of Leicester Physics Dept. to modify the Krolikowski

programme to include the effects of both Auger and electron—plasmon

processes.   These modifications were successful and, in view of

the results given in 3.4.2. regarding the effects of variation

of l_p and the excessive computer time needed to generate EDC's,

it was decided this programme would be adequate for the

interpretation of the results obtained in this work.

The programme was used in the following manner to obtain

an optical density of states for each material.   Using an

arbitary density of states as a starting point (usually obtained

from the 21.2 eV EDC with the background subtracted), the

scattering length l_e was altered on an iterative basis to obtain

a match between the predicted yield and the experimental yield

at 7.7 eV.

The predicted EDC was then examined and the initial

density of states modified (again on an iterative basis) until

there was good agreement between predicted and experimental EDC's

at 7.7 and 10.2 eV. Figure 3.7 shows the flow chart for this

process. Figure 3.8 shows the resulting EDC's for liquid

indium at 10.2 eV. T1 is the initial density of states from

the 21.2 eV EDC, T2 is the first modification made, as described

above, and T3 is the final optical density of states.

In all cases considered it was found to be unnecessary

to take into account the possibility of there being structure

in the density of states above the Fermi energy. A free

electron density of states was used in all cases and was found

to be perfectly adequate (this is not true for other metals −

Wotherspoon (1978) found that for bismuth, using the same

technique, the existence of structure in this region had to be

considered).

So far there has been no consideration of experimental

broadening effects. After the final optical density of states

had been arrived at, this was deconvoluted assuming the broadening

to take the form of a Lorentzian distribution (i.e. a delta

function would be reproduced as a curve described by the equation

$$g(x) = \frac{\Delta x}{2\pi\left[(x - x_0)^2 + (\Delta x/2)^2\right]} \qquad (3.16.)$$

where x is the half−width and x_0 is the position of the centre

of the curve). The deconvolution was done on an iterative

basis i.e. a trial density of states was convoluted compared with

the final optical density of states and then modified until
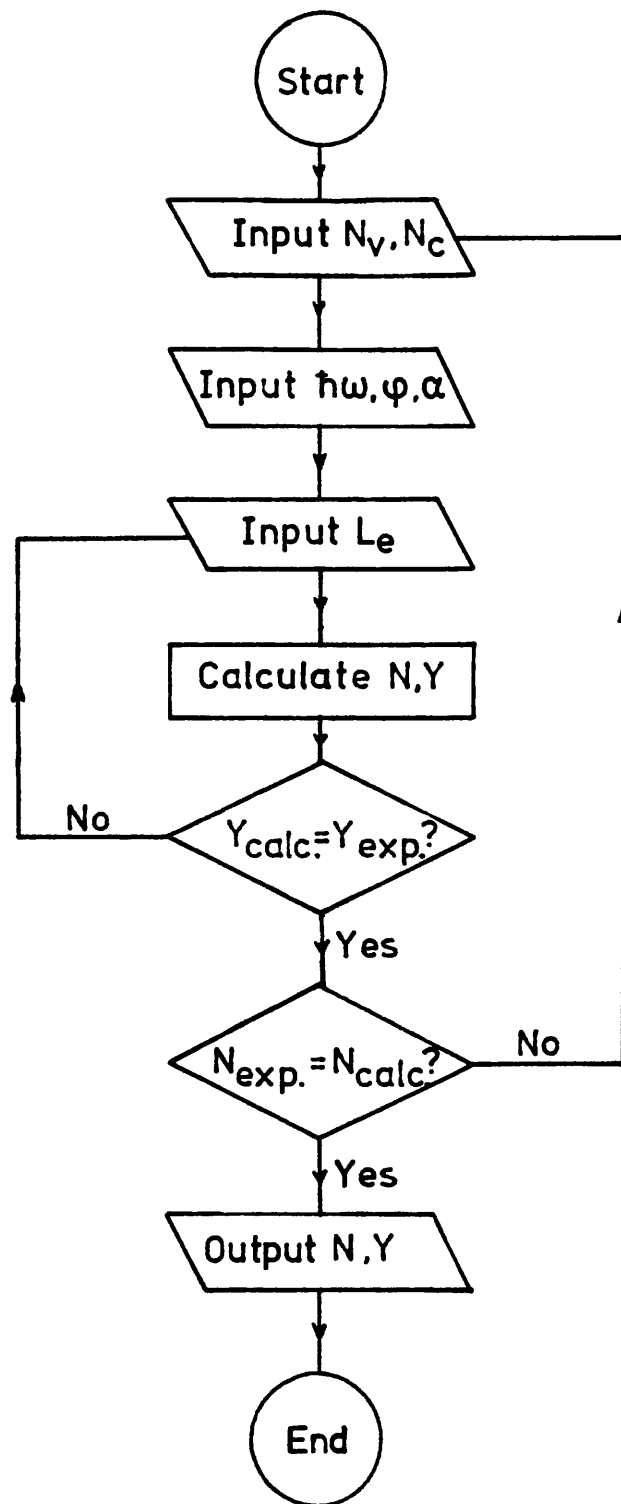

Fig.3.7- Flow chart for the calculation of an optical density of states
Fig. 3.8 - Trial densities of states for liquid Indium

agreement between the two was reached.

Strictly speaking this deconvolution should have been used on the final EDC to obtain the optical density of states. However it was found that applying the process to the optical density of states already obtained gave an adequate result and, since this was far less time consuming, this technique was adopted.

The optical densities of states obtained are given in the chapters on the different materials.   Also shown are the predicted EDC's based on the optical density of states.   In these both the total EDC (as a sum of both the primary (Y_p) and background (Y_b) yields) and the contribution due to the background emission (i.e. secondary yield and Auger yield etc.) are indicated.

Typical results for indium give the following yields:-

$h V = 7.7$ eV

        Primary yield $= 0.0034$ electrons/abs. photon

        Secondary " $= 0.0005$ electrons/abs. photon

        Auger   " $= 0.0001$ electrons/abs. photon

$h V = 10.2$ eV

        Primary yield $= 0.0047$ electrons/abs. photon

        Secondary " $= 0.0015$ electrons/abs. photon

        Auger   " $= 0.0002$ electrons/abs. photon

CHAPTER 4 :—   THE EXPERIMENTAL APPARATUS

In this chapter, the apparatus used in this study, the experimental technique, and the possible sources of error are discussed. There are, of course, considerable difficulties involved in the experiment. Extreme surface cleanliness is required, making it necessary both to prepare and keep the surface in ultra high vacuum, and the photocurrents involved are very small, so that highly sensitive electronics are needed for their detection.

The apparatus required for a photoemission experiment may be considered in three main sections. Firstly a source of photons capable of covering the necessary energy range, secondly a vacuum system capable of allowing the preparation and maintenance of an atomically clean surface, and thirdly an electronic system to detect and analyse the photoelectron spectra. Figure 4.1. shows the basic layout of such a system. The apparatus was, of course, under continuous development during the course of the study and it is the final version, with which the major part of the work was done, which is described here. Any modifications required for a particular material are described in the chapter relating to that material.

4.1.   The Optical System

Two different photon sources were used for this work, covering the energy range 3 - 21 eV. Since the largest of the valence bands is that of aluminium at 11.1 eV, this means that the whole of the valence bands of all materials used could be studied, and the core states of mercury could also be investigated.

4.1.1.   Photon Energies < 12 eV

The range of photon energies from 3 - 12 eV was covered

by use of an Hinterregger hydrogen discharge lamp, which gives

several strong spectral lines between 11.2 eV and 7.6 eV and a

continuous spectra below 6 eV. A typical lamp output spectrum

is shown in Figure 4.2. Individual photon energies were

selected by coupling the lamp to a 1 metre diffraction grating

monochromator (Hilger and Watts type 760). This uses a Bausch

and Lomb 3-section 600 line/mm. diffraction grating blazed at

1500 $\overset{o}{A}$ with a dispersion of 16.0 $\overset{o}{A}$/mm. at the exit slit. The

grating could be rotated either by hand or automatically by

means of a variable speed motor. The lamp was modified following

an investigation into the possibility of increasing the output

by inclusion of a heated filament in the discharge as described by

Eastman (1972). Unfortunately this technique was found to be

unreliable in operation and damaging to the grating, but it was

discovered however that the use of a water-cooled stainless

steel cathode (instead of the standard air-cooled aluminium one)

resulted in a far more stable lamp output, and the lamp required

cleaning much less often.

Typically the lamp output over the range 7 - 10 eV was

stable to <5% over a period of several days (including a complete

shutdown of the system overnight), and was stable to < 2% over a

period of 24 hours. The lamp was differentially pumped through

a 1 cm. length of 1.5 mm. bore pyrex capilliary connecting it to

the monochromator, which replaced the normal entry slits. This

enabled the lamp to be run at a pressure of 0.4 torr whilst

maintaining the monochromator at 7 x 10^{-5} torr. Typical

⟶ Photon Energy (eV)

Monochrometer output (arb. units)
Fig. 4·2 – Output spectrum of the hydrogen lamp

operating current and voltage were 400 mA, 800V DC. An attempt was made to pump the lamp separately using a LiF window between the lamp and the entry slit, so that the lamp could be run at higher pressure, but the static charge caused by the ionizing radiation attracted oil vapour to the window causing a rapid degradation of its transmission.

The monochromator was mounted horizontally and was pumped by a 4" oil diffusion pump using a freezer baffle and Convalex 10 oil to minimise vapour contamination of the grating. Since the system was horizontally mounted, a 2-mirror system was used to bring the photons normally onto the liquid surface. These mirrors were fixed in an evacuated brass tube using adjustable mountings to allow the focussing of the light onto the liquid surface. The tube was coupled to the exit slits of the monochromator and to the window flange on the chamber. The mirrors were front silvered aluminium, coated with MgF_2 and had a reflectivity of >80% at 1216 Å. The tube also contained a quartz filter which could be inserted in the beam path to remove second order effects when working at low photon energies. Instead of coupling the tube to the chamber it could be coupled to a fitting which mounted a sodium salicyclate phosphor in front of a photomultiplier tube (EMI 6256B) enabling a relative measure of the lamp output to be obtained. The fitting also allowed the LiF window from the chamber to be placed in the beam path so that its transmission could be measured.

4.1.2.   Photon Energies > 12 eV

This range of energies was covered by a noble gas

discharge lamp utilising either helium or neon. This gave
photons at the resonance energy of the gas - either 16.8 eV
(Ne I) for neon or 21.2 eV (He I) for helium. Higher energy
discharge lines exist for both gases but due to their low
intensity they were not used in this study. The construction
of the lamp is essentially the same as that used by Broden,
Hagstrom and Norris (1973) with the exception of an 'in-line'
Hinterregger-type anode-cathode arrangement. It was connected
to the chamber by being directly mounted onto the top flange
above the electron analyser, replacing the lithium fluoride
window and optical system used for low energy work. The lamp
was differentially pumped directly below the discharge by a
rotary pump, and between the two narrow-bore light pipes by a
diffusion pump. This dual pumping system enabled a pressure
of $<10^{-9}$ torr to be maintained in the chamber whilst there was a
pressure of 8 torr in the discharge capilliary. Typical operating
current and voltage were 100 mA, 800V DC.

    The gas used in the lamp was of commercial grade and
was purified by passing through filters of activated charcoal
cooled by liquid nitrogen. The gas extracted from the lamp,
immediately below the discharge, by the rotary pump could be
recirculated by passing through an activated alumina trap and
then again through the charcoal traps to remove any traces of
oil.

    An estimate of the contribution of hydrogen contamination
to the lamp's spectral output could be gained by insertion of a
LiF filter (cut-off at 12.6 eV) between two of the capilliary
sections.

4.2.   The Vacuum System

Experiments involving the measurement of low energy

(< 200 eV) electrons ejected from conductors, whether ultra-

violet photoelectron spectroscopy (U.P.S.), low energy electron

diffraction (L.E.E.D.) or Auger electron spectroscopy (A.E.S.),

tend to be very surface sensitive due to the low electron mean

free paths in the contamination layer.   Thus it is essential that

the surface be prepared and maintained free of contamination.

However, a clean surface in air at atmospheric pressure will be

covered in a monolayer of oxide in 10^{-6} seconds (if a unity

sticking coefficient is assumed), and a practicable experiment

of this type takes minutes at the very least.   This requires

that the experiments be performed in UHV (i.e. pressures < 10^{-9}

torr) and, due to the high vapour pressure of liquid metals, a

special technique must be devised to prepare a clean surface.

4.2.1.   The Experimental Chamber

The preparation and measurement were carried out in a

single stainless steel chamber in the form of a cylinder 6" in

diameter and 15" long (see Figures 4.3. and 4.4.), at one end of

which was fitted a 5" diameter observation window and at the other

the main analyser flange.   On top of the chamber were mounted

two ports, to one of which was fitted the sample preparation

flange, the other being fitted with a LiF window and connected to

the light tube.   On the side of the chamber were mounted an

ion gauge, a linear motion drive holding a small stainless steel

bucket to catch waste material from the pourer, and a flange

supporting a gold evaporation assembly to provide a standard

for yield measurements. The latter consisted of a small stainless steel plate mounted on a magnetic drive which enabled it to be moved from underneath the screened evaporation filament to directly below the aperture in the grid screening where the sample was normally placed. All flanges were sealed with Conflat[⊕] knife edge seals and OFHC copper gaskets.

4.2.2. The Pumping System

At the commencement of this study, it was expected that there would be difficulties in pumping the chamber due to the large vapour transport anticipated with liquid metals. For this reason a pumping system consisting of a water cooled Titanium sublimation pump (T.S.P.), and a 3-stage mercury diffusion pump (Edwards UHVM2A) was chosen. This was backed by a 2" mercury diffusion pump and a rotary pump (Edwards ED50). The top of the main pump was fitted with a liquid nitrogen trap and a thermoelectrically cooled chevron baffle. Oil backstreaming was prevented by two molecular sieve filters connected above the rotary pump. A base pressure of $< 3 \times 10^{-10}$ torr could be achieved after a 12 hour bake at $250^{o}C$. (The baking temperature being limited by the AgCl seal on the LiF window). The residual partial pressure of mercury after bakeout, as measured by mass spectrometer, was $\approx 2 \times 10^{-12}$ torr. The principal contaminants remaining in the system were H_2O, N_2 and CO.

In practice, except in the case of mercury, vapour transport was found not to be a problem, and later an ion pump (Ferranti 220l/sec) — TSP combination was successfully used instead.

The pumping system and chamber were mounted on a trolley to enable bakeout to be carried out away from the optical system.

4.2.3.   The Crucible Flange

The extreme surface cleanliness required in a photoemission experiment raises several problems. Owing to the ease of evaporation of liquid metals, it is not always possible to use heat cleaning, as this could result in loss of the sample. Simply melting cleaned solid indium has been tried (Koyama 1968), but it has proved virtually impossible to remove oxide from the surface. Argon ion bombardment has also been tried (Stevenson 1968) but this has been unsuccessful - possibly because the surface is mobile and non flat.

The method decided upon was that of pouring from a crucible. This has been used before (Stevenson loc.cit.), but in the present case had two important additions. Firstly the entire crucible was mounted within the vacuum chamber, enabling the material to be outgassed in a good vacuum at a temperature well above the working temperature without evaporation in the working area, and secondly the crucible had a re-entrant tube to allow pouring from the centre of the melt which was free of oxide film or heavy contaminants. The success of this technique may be seen from the results given later, this being the only monitor of surface cleanliness.

The construction of the crucible is shown in Figure 4.5. Crucibles of three materials were used - stainless steel, quartz and alumina. Those of steel and quartz were heated by electron bombardment from a thoriated tungsten filament (the quartz having been covered in an outer sheath of several layers of 0.002" stainless steel). With +2000V applied to the crucible, and an emission current of 40 mA, temperatures in the region of $700^{\circ}C$

were achieved. The alumina crucibles were heated (up to $900^{o}C$)

by a tungsten filament wound round the outside. These alumina

crucibles lacked a re-entrant tube, due to manufacturing

difficulties, and heavy contaminants were removed by allowing

several drops of metal to fall into the waste trap before pouring

the sample. All crucibles were sealed by alumina rods which were

carefully ground in to achieve a good seal. With alumina and

quartz crucibles, care was needed when heating to avoid thermal

shock to the materials.

4.2.4. The Photoelectron Analyser.

The electron analyser itself was a retarding field

instrument. It had 3 electrodes - the specimen table and an

aluminium hemispherical collector 4" in diameter inside which was

mounted a hemispherical grid of stainless steel mesh (0.001"

diameter wire, >90% transmission), three inches in diameter. A

flat plate of 0.005" stainless steel covered the bottom of the

hemisphere. Holes 1" in diameter in the centre of the collector

and the bottom plate allowed for the passage of photons and

photo-electrons. To even out the work function of the inside of the

collector, it was coated in a layer of fine carbon. This was

achieved by spraying a suspension of graphite in alcohol over

the surface with an artists' air-brush, giving a very even

greyish appearance to the inside. A retarding field was applied

between screen and collector, and a fixed potential between

screen and specimen. The whole assembly was mounted upon a

stainless steel yoke affixed to a stainless steel plate which was

secured to the main flange by four $\frac{1}{2}$" diameter steel rods, this

mounting allowing the centralisation of the light aperture under

the LiF window. Whilst other forms of electron analyser are known to give better resolution, a retarding field type was chosen since it could be used even when there was considerable evaporation and condensation from the heated sample.

The specimen table (Figure 4.6.) consisted of a 1" metal or alumina dish. It was recessed on the underside to accept a tungsten wire heating filament which was held in place by a flat stainless steel plate and insulated with alumina washers. The whole was supported on a 3/16" diameter alumina rod in a 1" cube of stainless steel, electrical connections being passed through the cube in alumina sheaths. A screen of 0.005" stainless steel surrounded the specimen assembly and was mounted on the cube with insulating washers. The cube was supported on the rods affixed to the flange by means of a yoke and could be moved by means of a magnetic drive. The screening around the specimen, whilst normally connected to the grid when in use, had a separate connection to a feedthrough on the flange so that shorting of the screen to the specimen did not necessarily terminate the experiment.

4.3.   The Detection System

The circuit used, shown in Figure 4.7., was a modified form of that used by Eden (1970). A balancing capacitor in parallel with the photo-diode was not used as this was found to be unnecessary, the grid screen reducing the out-of-phase AC pick-up sufficiently for it to be suppressed by the phase sensitive detector.

was varied by a ramp generator modulated at 15 - 20 Hz, the frequency being chosen to minimise the effects of 'beating' in the electronics. Typical modulation voltage was 0.4V p-p. Photoelectrons travelled first to the screen, which was maintained at a fixed potential with respect to the specimen and then across the retard potential to the collector. The current resulting was then amplified by means of a Keithley 427 current amplifier. High frequency noise and D.C. bias were eliminated by means of the amplifier's variable rise time and D.C. offset facilities (typically 10^{10}V/A amplification, 30 ms rise time).

The signal was then analysed by a phase sensitive detector (PSD) (Brookdeal 401A) and fed directly into the Y amplifier of a chart recorder. Since the X signal for the recorder was taken from the ramp generator, and the photoelectron signal was differentiated in the PSD, a direct plot of the photoelectron energy distribution could be obtained. By using a slow ramp voltage (typically 40 secs/volt) and a long time constant on the PSD (typically 3 secs), a very low noise trace could be obtained. Noise level is indicated in Figure 4.8.

For measurements of the yield, the collector and grid were connected together and biased to +25V. The current amplifier was connected between the specimen and earth and the output fed directly to the XY plotter, giving a measurement of the total photoelectron current from the specimen. The maximum rise time (300 ms) was used to eliminate noise, and extreme care was taken with the earthing and screening. Zero calibration was by interruption of the light source and, with care, currents of $<10^{-13}$ amps could be measured.

4.4. Experimental Procedure

Setting up. Before assembly the flanges and chamber were thoroughly cleaned with a degreasing agent. Alumina and quartz parts were cleaned by heating in an air oven to $900^{o}C$, molybdenum parts by heating in vacuo to $1500^{o}C$ using a radio frequency induction heater. Small stainless steel parts were cleaned by electropolishing.

The crucible was filled with material that had been scraped clean of oxide and then cut into small pieces. After assembly of the system this material was then melted under vacuum, the crucible flange removed and the process repeated until the crucible was filled.

After leak testing, the chamber was baked at $250^{o}C$ for periods of up to 24 hours and towards the end of this bake, the specimen table and crucible heaters were switched on for initial outgassing. Final outgassing of both was done at near their maximum attainable temperatures when the chamber was cold. The cleanliness of the specimen table may be judged from Figure 4.8 which shows EDC's taken from a molybdenum specimen table after outgassing. Finally the electronics and optical system were connected to the chamber.

The table was then cooled to below, and the crucible to just above, the melting point of the material. A few drops of material were poured into the trap in the system to clean the pouring tube of the crucible, and the specimen table was then moved into position below the crucible and filled. The material having been allowed to freeze (to minimise the danger of spillage with possible shorting of connections), the table was moved back

into position below the analyser.

A series of EDC's were then taken for both the solid and liquid material for the energy range of the lamp in use. The other factor of interest was, of course, the yield of the material and this was measured for both solid and liquid before the EDC's were taken, as a clean surface was vital for this measurement.

The wavelength setting of the monochromator was scanned automatically across the full energy range of the lamp (the quartz filter being used below 6 eV to remove second order effects) and a plot of photocurrent against wavelength obtained on the chart recorder. Following this, the lamp was calibrated using the gold evaporator. The cleanliness of the gold surface was checked by taking an EDC and comparing it with published data (Nilsson, Norris and Wallden 1971). Since the work function of the materials in this study is less than that of gold (5.6 eV), lamp calibration below 5.6 eV was achieved by measuring the lamp output using the salicyclate phosphor and photomultiplier, correcting this for the LiF window by measuring its transmission at the end of the experiment. By fitting this to the known output above 5.6 eV, the result could be used as a sub-standard below 5.6 eV.

4.5. Analysis and Treatment of Results

4.5.1. The Yield and Work Function

The yield of a material may be specified either as electrons/absorbed photon or electrons/incident photon. Using a gold standard to calibrate the lamp, the yield/incident photon could be calculated from the data already available. The yield/absorbed photon Y_m was obtained using published reflectivity data

to evaluate the expression:

$$Y_m = Y_g \times \frac{(1 - R_g)}{(1 - R_m)} \times \frac{I_m}{I_g}$$

(4.1.)

where:

R = reflectivity,   I = photocurrent,   m= material,   g = gold

The yield having been calculated, the work function was then calculated from a Fowler plot of $Y^{\frac{1}{2}}$ against photon energy. Y_g and R_g were taken from Krolikowski's work (see Figure 4.9.), R_m from suitable published data where available.

4.5.2.   Normalisation of EDC's

The yield of the material having been determined, the EDC's were normalised by digitizing the spectra, then using a Simpson's rule integration to determine the area encompassed by the EDC and hence the total photocurrent represented.   The spectra could then be multiplied by the appropriate factor to achieve normalisation.

4.6.   System Resolution

The resolution of the system was determined empirically from the width of the Fermi edge on the EDC's (typically 0.4 eV from 10% - 90%), this width appearing to be independant of specimen temperature.   There are several factors which may contribute to this broadening.

4.6.1.   Optical Broadening

The monochromator does not, of course, provide a truly monoenergetic source of photons, though the value for dispersion quoted by the manufacturers is quite small (16 Å/mm).   Since the lamp is being operated in a windowless, slitless mode through a capilliary of ϕ = 1.5 mm., and the exit slit must be wide open at
Fig. 4.9 - Quantum yield of gold (used as reference)

1.5 mm. to give an adequate signal/noise ratio, the monochromator

is operating under the worst possible conditions. However the

calculated value for the dispersion is still quite small

(= 0.2 eV at 10.2 eV in the worst case) and this is borne out by

examination of the variation of Fermi edge width with exit slit

width which appears to be negligible.

4.6.2. Modulation Broadening

This arises from the necessity of having a modulated

ramp voltage so that phase sensitive detection may be used to

obtain a good signal-to-noise ratio. Since the magnitude of

the modulation is known, an estimate may be made of the broadening

due to this source, and Figure 4.10 shows a computer simulation

of the effects of the modulation upon various features such as

the Fermi edge. This simulation indicates that the value of

the broadening expected for the modulation normally used (0.4V p-p)

is approximately 0.4 eV and hence implies that this is the

predominant broadening mechanism present in the system. The

variation of the edge width observed with modulation voltage

appears to bear this out. The problem has been dealt with in

some detail by Houston and Park (1972) but since the present

work uses only a simple sine wave modulation, a simplified

numerical approach appears to give adequate results.

4.6.3. Field Distortion

If the specimen to be dealt with was a point source at

the centre of a perfectly spherical collector there would, of

course, be no broadening from this source. In practice, however,

the specimen is in the form of a flat dish 1" across and the
Fig. 4·10 -Effects of modulation broadening on EDC s

light spot is of a finite size (≈ 2mm. x 1mm.). The exact

effect of this is rather hard to determine but has been covered

in some detail by Di Stefano and Pierce (1970) who showed that the

use of a fine screen between the specimen and collector could

result in a considerable improvement in the system resolution

(of the order of 0.1 eV for electrons with kinetic energies of

several volts). There were some variations in system geometry

made during the course of the work (notably in the vertical

position of the specimen table), and these appeared to have

little effect on the final resolution.

4.6.4. Magnetic Distortion

The presence of a magnetic field near the analyser

can cause distortion of the electron trajectories between

specimen and collector. Some care was taken to avoid this

effect, particularly in the case of the ion pumped system, by

the use of screening. No magnetic distortion could be

observed on bringing a small horseshoe magnet near the system —

so this appears to have been eliminated as a significant

source of broadening.

4.6.5. Work Function Distortion

Variation of the work function of the collector or the

specimen surface may also result in distortion of the EDC's.

However Di Stephano and Pierce (loc.cit.) showed that this is

only a problem when large crystallites ($>10\mu$) are present, and

the technique adopted of coating the collector surface with

colloidal graphite appeared to be successful in eliminating errors

from this source. In the case of the specimen itself there is the

problem of fringing fields from areas of the emitter with a

different work function. However the use of a large specimen

should reduce this effect, and an angular analysis of the

photoemitted electrons given by the computer programme of

Chapter 3 indicates a strong bias towards emission normal to the

surface which is the direction of minimum distortion of the field,

which would also tend to reduce the effect. The use of an

emitter screen (see Figure 4.6.) connected to the specimen acts

as a guard ring and further reduces the distortion of the field.

CHAPTER 5:—   INDIUM AND ALUMINIUM

5.1.   Introduction

Indium and aluminium have long been regarded as highly

free electron like in the liquid state and as such were fairly

obvious starting points for this work.   Both metals are in

Group IIIA (Al: $3s^2 3p$; In: $5s^2 5p$).   The structure of aluminium

is face centered cubic (f.c.c.) in the solid phase and hard

sphere like in the liquid.   Solid indium is basically f.c.c.

with some small tetragonal distortion.   In liquid indium the

structure factor $S(q)$ is very similar to the result expected

on the basis of a hard sphere assembly, except for a small

asymmetry in the first peak (Ocken and Wagner 1966) consistent

with distortions found in the solid phase.

As mentioned in Chapter 1, transport properties and

other measurements for both these materials are consistent with

the free electron picture.   There is little previous spectroscopic

work in the liquid state — liquid aluminium has been examined by

soft X-ray spectroscopy by Caterall and Trotter (1963) and

Fabian (1972),and although some features were apparent, little

difference was observed between solid and liquid.   Liquid

indium has been examined by UPS by both Koyama (1968) and

Stevenson (1968).   However both sets of results showed large

scattered electron peaks and hence there still exists some doubt

as to the UPS spectra of indium.   In the solid, evaporated

films of both materials have been studied, aluminium by Wooten

et al (1966), indium by Koyama (loc.cit.), and both by Pollak

(1972) using XPS.

In this chapter, results are presented for indium and

aluminium in both solid and liquid states. They will be analysed

in terms of the 3-step approach using both Monte Carlo and

analytical approaches as detailed in Chapter 3.

5.2.   Indium

5.2.1.   Experimental

Indium was chosen as the initial subject for investigation

as it presented the fewest problems from an experimental point of

view. Indium is a ductile metal of low toxicity with a melting

point of 154°C. It is not highly reactive in the liquid state

and may be contained with ease in austenitic stainless steel

(Liquid Metals Handbook 1955). The only problem arises from

its low surface tension which, whilst making it easy to pour,

does mean that care must be taken over the seal of the crucible

and in moving the specimen table.

The optical properties of indium in the U-V are fairly

well documented, having been measured both by Wilson and Rice

(1966) and Koyama (loc.cit.). Also of note is a very careful

measurement by Van Laar and Scheer (1965) of the photoyield of

evaporated indium films near to the threshold. There has also

been considerable theoretical work on indium, and densities of

states have been published by Koyama and Spicer (1971), Ashcroft

and Lawrence (1969), Shaw and Smith (1969), and Chan and

Ballentine (1972).

The results given here are from a series of four

experiments, and some preliminary results have already been

published (Norris et al 1973). An effect noted in the later

work on this metal, and also during work on lead, is that the

rate of freezing of the liquid can affect the structure observed

in the solid. Contrary to normal expectation, rapid freezing

of the melt (i.e. heater suddenly turned off) was found to give

much more distinct structure than slow freezing (i.e. heater

power slowly reduced). This effect is believed to be due to

the presence, observed in some specimens, of a light skin on

the surface of the specimen which broke up in the centre on

melting (probably due to convection effects). Although tracking

of the light spot over the specimen revealed no difference in

solid EDC's due directly to its presence it may, by acting as

a source of condensation nuclei during slow freezing when it

was allowed time to reform, have prevented the formation of large

single crystals.

5.2.2. Yield of Indium

Figure 5.1. shows the yield of indium for the liquid and

both the rapidly and slowly frozen solid. The overlay is the

results of Koyama for liquid, frozen liquid and crystal specimens.

The reflection data used was from Wilson and Rice (loc.cit) for

the liquid and from Koyama (loc.cit.) for the solid. The two

sets of results are in good qualitative agreement, the difference

in magnitude probably being due to the difference in surface

cleanliness. The similarity between the behaviour of the

rapidly frozen solid in this work and the crystal specimen in

Koyama's work (relative to the liquid in both cases) gives

support to the idea that the rapidly frozen solid consists of

large single crystals. The major features of the yield are

peaks at 6.9 eV, 8.9 eV and 10.7 eV with corresponding dips

at 5.8 eV and 7.9 eV. The lower two peaks correspond with

The figure shows a plot titled "YIELD OF INDIUM" with:
- Y-axis: Y(ω) (Electrons/absorbed photon), ranging from 10^{-5} to 10^{-1}
- X-axis: Photon Energy (eV), ranging from 4 to 12

Legend:
—— liquid
— — — solid (rapidly frozen)
—·—·— solid (slowly frozen)

peaks observed in the XPS work of Pollak and will be discussed

in more detail later.   Also in indium there is a free electron

surface plasmon which occurs at 8.7 eV (Koyama and Spicer loc.cit.).

Figure 5.2. shows a yield prediction for indium using

the Monte Carlo technique of Chapter 3.   Assuming an l_p of $17\overset{o}{A}$,

a comparison of this with the measured yield at photon energies

of 10.2 and 7.7 eV indicates a value for l_e of approximately

$14\overset{o}{A}$ at 8.5 eV above the Fermi level.   The comparatively low

variation of yield with l_p indicates why this change in yield

between solid and liquid is small.   However the value for l_e

differs considerably from that of $200\overset{o}{A}$ obtained by Koyama to

fit his yield at high photon energies.

Fowler plots (see Figure 5.3.) give a value for the

work function of 3.94 ± .07 eV in the liquid state and 4.06 ± .1 eV

for the solid.   These values agree well with those of other

workers for the solid (Koyama 4.13 ±.05 eV, Stevenson 4.07 eV,

Van Laar and Scheer 4.08 ±.01 eV) and with Stevenson's value

for the liquid of 3.96 eV.   It does not agree with the value of

4.15 eV obtained by Koyama for the liquid.

5.2.3.   Liquid Indium EDC's

Figure 5.4. shows EDC's for liquid indium at low photon

energies taken at approximately $50^{o}C$ above the melting point.

The measurements were repeated on two other specimens without

significant change.   Clear features may be discerned — notably

a sharp peak at the Fermi edge, a peak at -1.7 eV and a dip at

-2.6 eV.   These features are constant in both strength and

position with changing photon energy.   In addition a weak

feature at -3.6 eV may just be discerned.   These results differ

slightly from those reported earlier (Norris et al loc.cit.) in that a weak dip at -1.3 eV is not now seen. This change is believed to be due to the temperature in the initial work being too close to the melting point, resulting in the existence of small regions of solid indium formed around impurities at the surface.

Figure 5.5. shows a comparison between the present work and that of Koyama and Spicer. These agree well in the position of the main minimum at -2.6 e V. In the present work, the comparative absence of a scattered peak at low energies and the appearance of structure is believed to be due to the improved resolution and surface preparation technique used. The admittance of air to the system was seen to cause a general degradation of the EDC's and a sharp increase in the scattered peak - seen in Figure 5.4. at low energy extreme. An attempt was made to see if a temperature variation could be observed in the EDC's,but no variation was apparent up to $\simeq 400^{\circ}$C,and attempts to raise the temperature above this point resulted in evaporation of indium onto the LiF window.

5.2.4. Solid Indium EDC's

Figures 5.6. and 5.7. show EDC's for solid indium both in the rapidly and slowly frozen states. The two minor features observed in both are identical in position but vary considerably in strength. They are firstly, a peak varying in position from -1.1 to -0.9 eV being notably stronger at the higher photon energies and secondly, a peak varying in position from -1.8 to -1.5 eV with increasing photon energy, being strongest at the intermediate energies. The main minimum is at -2.4 eV at all

photon energies. In the rapidly frozen solid there is also a strong feature at -3.1 eV. This feature is seen in a weaker form at -3.6 eV in the slowly frozen solid, and a weak dip at -4.4 eV is just discernable. Figure 5.8. shows a typical frozen indium surface.

The experimental EDC's were compared with theoretical EDC's from calculations by Koyama and Spicer (1971). These calculations were based on the 3-step model, assuming direct transitions and adopting the method given by Koyama and Smith (1970) for aluminium. Due to the tetragonal distortion of the f.c.c. structure in indium the calculation is rather more complex, involving the division of each 1/16th symmetry segment of the Brillouin zone in unequal parts and solving the appropriate 4-OPW equation for each. The use of unequal segments (done to reduce computing time) results in some mismatch in the energy bands, but this was found not to be significant when the final result was calculated.

In each sector Koyama and Spicer solved an equation of the form:

$$O = \begin{vmatrix} T_1(\vec{k}) - E_i(\vec{k}) & V_{111} & V_{111} & V_{200} \\ V_{111} & T_2(\vec{k}) - E_i(\vec{k}) & V_{002} & V_{111} \\ V_{111} & V_{002} & T_3(\vec{k}) - E_i(\vec{k}) & V_{111} \\ V_{200} & V_{111} & V_{111} & T_4(\vec{k}) - E_i(\vec{k}) \end{vmatrix} \quad (5.1.)$$

where

$$T_1(\vec{k}) = \vec{k}^2 \qquad T_2(\vec{k}) = (\vec{k} - \vec{K}_{111})^2$$

$$T_3(\vec{k}) = (\vec{k} - \vec{K}_{111})^2 \qquad T(\vec{k}) = (\vec{k} - \vec{K}_{200})^2$$

These features are
damage caused in
removing the
sample from the
system
Fig. 5.8 - Surface of frozen Indium

$E_i(\vec{k})$ are the eigen values for the energy bands, V_k are the Fourier coefficients of the potential arising from the k th. lattice wave vector.

Figure 5.9. shows the comparison of calculated and experimental EDC's. It may be seen that the agreement in the position of structure close to the Fermi edge, particularly in the peak at -1.8 eV, is good. Whilst the agreement between the strengths of the features is less good, it should be remembered that the analysis takes no account of matrix elements or of the possibility that the escape probability may vary with the different crystal faces.

5.2.5. High Energy EDC's

Figure 5.10. shows high energy EDC's for both solid and liquid indium. There is a large scattered background which makes comparison with the low energy spectrum difficult. However, there appears to be good correspondence in the structure, particularly near the Fermi edge in the feature at -2.6 eV which shows clearly in both solid and liquid. A dip is also observed at -3.6 eV in both solid and liquid, corresponding to the weak feature observed in the low energy EDC's. Closer to the Fermi edge in the liquid EDC it is possible to discern the feature at -1.7 eV observed before, and in the solid the features are observed at -1.0 eV and -1.8 eV corresponding to those seen at low energies. The solid appears to be in the rapidly frozen form. Moving towards the low energy end of the EDC, a break in slope may be observed at -8.6 eV. This value corresponds well with the value calculated by Kittel (1968) for the bottom of the free electron band. The hump lower in energy centered at

approximately -11 eV corresponds in position with a bulk plasmon

observed by Pollak (loc.cit) at 11.7 eV and, at the extreme low

energy end of the EDC, the strong peak at -17.1 eV is in good

agreement with the position of the 4d peak (also observed by

Pollak).

5.2.6. <u>Optical Density of States</u>

The high energy end of the liquid EDC, with the background

subtracted, was used as a basis for calculating an optical density

of states.   Figure 5.11 shows the density of states thus obtained

compared with the XPS spectrum obtained by Pollak from an

evaporated film of indium.   It may be seen that there is broad

agreement in the presence of a feature at -3.6 eV, although the

other feature observed by Pollak at -4.2 eV is not seen.   This

trial density of states was used in the modified Krolikowski

programme (as detailed in Chapter 3) to obtain a final optical

density of states.   The scattering length used in the programme

was selected to give agreement between calculated and experimental

yields at 7.7 eV.   The final density of states thus obtained is

shown in Figure 5.12 compared with a free electron curve.   It

can be seen that there is considerable disparity between the two.

Figure 5.13 shows the comparison of simulated EDC's using these

two densities of states with the experimental curves at 10.2 and

7.7 eV.   The value for the absorption coefficient was taken from

Lemmonier et al (1969).   The value of l_e used was 14Å.   This

is considerably shorter than the value of $l_e = 50$Å used by

Koyama (loc.cit.) to fit the yield at low photon energies.

However, the yield obtained in this work is considerably lower,

probably due to the increased surface cleanliness, and the

present result is in good agreement with the work of Brundle (1974).

------- Solid density of states from
Koyama and Spicer (1971)
Fig.5.12 - Final optical density of states for Indium
Fig.5.13–Comparison of calculated & experimental EDCs for liquid indium

In Figure 5.12 the final optical density of states is compared

with the density of states obtained by Koyama for the solid.

This is shown since the densities of states published for the

liquid (Shaw and Smith 1969 and Chan and Ballentine 1971) are

essentially featureless. It may be seen that there is good

agreement in the position of the main maximum at $=$ 4 eV and in

the main minimum at $=$ -3 eV. The agreement is less good

closer to the Fermi edge. The densities of states for the

solid obtained by Shaw and Smith (loc.cit.) and Ashcroft and

Lawrence (1968) are in less good agreement - Shaw and Smith

placing the main maximum at $=$ -3 eV and Ashcroft and Lawrence

placing it at $=$ -5 eV.

5.2.7. Discussion

There are several features of note in these results.

Firstly, although the structure observed in the liquid shows

behaviour characteristic of non-direct transitions, whilst that

in the solid is characteristic of direct transitions (particularly

in the rapidly frozen form), the broad density of states features

remain unchanged. This implies strongly that aspects of the solid

state band structure persist on melting - notably the peak at

$=$ -4 eV with an associated dip at -2.6 eV. These may be

related to the large band gap at the L face of the Brillouin

zone. Secondly, the fact that the broad density of states

features remain unchanged over a large range of energies (including

the XPS results of Pollak) indicates that the effect of matrix

elements is not significant since these would show an energy

dependance.

The good agreement between the theoretical EDC's calculated using a 3-step model with non-direct transitions, and the experimental EDC's is highly encouraging.

5.3.   Aluminium

5.3.1.   Experimental

Aluminium is an archetypal free electron metal and, as such, has naturally attracted a lot of interest both from a theoretical and practical viewpoint.   Experimentally it was the most difficult to handle of the materials used.   Liquid aluminium is very corrosive (Liquid Metals Handbook 1955), necessitating the use of an alumina crucible and specimen table, and, due to the relatively high expansion coefficient of solid aluminium, considerable problems were encountered with cracking of these crucibles.   The high surface tension of the liquid also made it very difficult to pour.   Further, the high specimen heater currents needed to maintain the aluminium in a liquid state resulted in a high background noise level.   However, since the oxide of aluminium is denser than the metal itself, even a fairly badly contaminated solid surface could be recovered by remelting.

The results given here are from two experiments, and some preliminary results have already been published (Norris et al 1974).

5.3.2.   Yield of Aluminium

Figure 5.14 shows the yield of aluminium obtained in the present work.   This is given in electrons/incident photon rather than electrons/absorbed photon for the purposes of comparison with the results of other workers.   Due to problems

● Wooten et al. (evapourated film)
Fig.5.14 - Yield of Aluminium

mentioned earlier with the high specimen heater current required, only isolated values of the yield of the liquid are given as the high background noise level made more detailed measurement impossible. However, the isolated results obtained agree well with the results for the solid. There is a known surface plasmon in aluminium at 10.4 eV, and the variation of the strength of this with surface roughness has been examined in some detail by Endriz and Spicer(1974). They examined a series of evaporated aluminium films of varying surface roughness over the range $X = 8 - 28\mathring{A}$ where X = the rms height variation of the surface. On the basis of these results they calculated the yield for a perfectly smooth aluminium surface. Their results for $X = 8\mathring{A}$ and $X = 28\mathring{A}$ are shown on diagram 5.13, with the calculated yield. It may be seen that their prediction of the yield for $X = 0\mathring{A}$ is in good agreement with the observed yield in this work at low photon energies, implying that the liquid surface is very smooth.

Faber (1972 P.91) has derived an expression for the estimation of the roughness of a free liquid surface of the form:-   f being the surface tension

$$X = \left(\sum \overline{\xi^2}\right)^{1/2} = \frac{k_B T}{4\pi f} \log_e\left(\frac{4\pi f}{d\,g\,a}\right) \quad (5.2.)$$

where ξ = the displacement due to a given ripple mode for a close packed surface, $a = 1.09 \, (^m/d)^{2/3}$, m = atomic mass, d = density. Filling in the appropriate values for aluminium, this gives a value for X of $2.08\mathring{A}$ which is in good agreement with the observed result for photon energies below 9.5 eV. Above

this energy the yield begins to rise sharply. The reason for this is not obvious since the lower energy result indicates that the plasmon effect should be small. However it is possible that, since the high surface tension of aluminium resulted in a sharply curved surface ($d \simeq 0.4$ cm.), that this effect is due to non normal incidence of the light on the specimen. This would result in the generation of photo—electrons closer to the surface than in the case of normal incidence, giving a higher yield, particularly at higher photon energies.

More surprising is the coincidence between the yields for solid and liquid. This suggests strongly that the solid surface retains many of the physical characteristics of the liquid — a suggestion that is borne out by the observation that the frozen surface was very liquid—like in appearance and remained non—oxidised for a considerable period of time after removal from the vacuum system. Figure 5.15 shows a typical frozen aluminium surface. Figure 5.16 shows a Fowler plot for solid aluminium. This gives a value for the yield of 4.02 ± 0.04 eV, which differs somewhat from the results of other workers (Riviere 1969).

5.3.3.   Liquid Aluminium EDC's

Figure 5.17 shows EDC's for liquid aluminium taken at low photon energies at approximately 50°C above the melting point. The major feature seen is a peak at -2.5 eV with a corresponding dip at -3.7 eV. However, there is also a very weak feature visible in the form of a peak at -1 eV. These features do not appear to vary with photon energy, although the peak at -1 eV is so weak that it is impossible to be sure

of this, so that the peaks may well reflect structure in the density of states. Attempts to work at higher temperatures were unsuccessful due to limitations in the heater design.

5.3.4.   Solid Aluminium EDC's

Figure 5.18 shows EDC's for solid aluminium at low photon energies. The major feature still occurs at -2.5 eV with a dip at -3.7 eV, and this is in good agreement with a feature observed both by Wooten et al (loc.cit.) and by Endriz and Spicer (loc.cit.). However there are also two other features in the form of very weak peaks at -1 eV and -1.5 eV which become stronger with increasing photon energy, though they are too weak for any changes in position to be discerned.

5.3.5.   High Energy EDC's

Figure 5.19 shows a set of EDC's for liquid aluminium obtained at 21.2 eV. Curve (c) is for freshly poured aluminium and shows features at -2.5 eV, -6.5 eV and -11 eV, the peak at -1.0 eV observed in the low energy EDC's not being resolved. Curves (a) and (b) show the same specimen after a period of time. The peak at -6.5 eV has increased sharply in strength showing clearly that this is due to contamination (aluminium has a very strong affinity for oxygen). The features at -2.5 eV and -11 eV appear unaffected and may well be characteristic of the pure material. The sharp edge at -10.2 eV interpreted by Lindau et al (1971) as being due to a plasmon loss does not appear, suggesting again that the surface is very smooth.

Figure 5.20 shows the high energy parts of the EDC for solid (b) and liquid (a) aluminium. These are very similar

Aluminium

except for the appearance of a small feature at —4.9 eV in the solid. They are compared with theoretical densities of states for the liquid from Chan and Ballentine (c) and for the solid from Ashcroft (d). Although no structure is apparent in the liquid density of states, it is noteworthy that the feature at —2.5 eV observed in the liquid and solid EDC's corresponds with a strong peak in the solid density of states.

5.3.6.   Optical Density of States

A free electron density of states was used as the basis for a repetition of the iterative process used for indium. Figure 5.21 shows the final optical density of states compared with a free electron density of states.

The theoretical curves are compared with the experimental results in Figure 5.22 at 10.2 eV and 7.7 eV. It may be seen that the use of a free electron density of states results in a far greater scattered background than is observed experimentally. The value of the yield obtained theoretically is not in agreement with that measured experimentally although the agreement of the EDC's is structurally good. The theoretical yield does however agree with the extrapolated smooth surface yield of Endriz and Spicer (loc.cit.). The values of absorption coefficient used were from Philipp et al (1964). The value of l_e required to give agreement with the measured yield at 7.7 eV was 18Å. This is much shorter than the value of $l_e = 70\text{Å}$ given by Wooten et al (1966) and is in good agreement with the results of Callcott and Arakawa (1975) for the solid. However, the smooth surface in the present work appears to remove most of the plasmon

ALUMINIUM

effects that could cause error in the estimation of l_e, and this may account for the above difference. In Figure 5.21 the final optical density of states is compared with the calculated density of states of Koyama and Smith (loc.cit.) for the solid. This shows good agreement in the position of the main maximum around -3 eV, but not in the structure closer to the Fermi edge. This density of states is used for comparison in preference to one for the liquid since these are essentially featureless (e.g. Chan and Ballentine 1971) as is the XPS result of Pollak (1972).

5.3.7.   Discussion

The results obtained for aluminium appear to generally confirm the picture presented for indium. The structure in the liquid again shows behaviour more characteristic of non-direct transitions, whilst that in the solid is characteristic of direct transitions. The broad features are, however, unchanged from solid to liquid and are also seen in the high energy spectra. The XPS result is featureless, but this may well be due to the generally poorer resolution in this technique. The major feature — the dip at -4 eV which corresponds with the onset of the second band — is weaker than the dip in indium. This is consistent with the smaller band gaps in the band diagram of aluminium and its generally more free electron like nature. However, as may be seen in Figure 5.21, the optical density of states still differs considerably from the free electron model.

CHAPTER 6:—   LEAD AND TIN

6.1.   Introduction

Lead and tin are both quadrivalent materials of group IVA. In the solid phase lead $(6s^2 6p^2)$ has a f.c.c. structure; metallic (white) tin $(5s^2 5p^2)$ has a body centered tetragonal structure. Both metals have been studied fairly extensively, but lead is of particular interest to liquid metal theoreticians as it has some anomalous properties. As stated in 1.4.3., measurements of the Hall effect for liquid lead give a result considerably different from that predicted by n.f.e. theory. Transport measurements also indicate a very low mean free path ($= 4\overset{\circ}{A}$). Over the past few years there has been considerable work done on the band structure of lead. Early OPW calculations by Anderson and Gold (1965) were followed by Loucks' (1965) Relatavistic APW calculation. More recently, band structures have been published by Breeze (1974) and McFeely et al. (1975), where particular attention has been paid to the splitting of the 6p band, attributed to crystal field effects by Breeze and to spin orbit splitting by Ley et al. (1972). Previous spectroscopic work on lead is confined to measurements of evaporated films by Norris et al. (1972), but since the conclusion of this work, further experiments have been done on the liquid by Wotherspoon (1978). XPS measurements have been done on evaporated films by Pollak (1972) and Ley et al. (loc.cit.).

Solid tin has also been the subject of considerable study, several band structures having been published, the most recent being those of Ament and de Vroomen (1975) and Craven (1969). However, spectroscopic data is confined to the results

of Pollak (1972), Hochst et al. (1976) and most recently Castelijns et al. (1977), all on evaporated films. Stevenson (1968) examined liquid tin but only at low photon energies.

In this chapter UPS results are presented for tin and lead in both solid and liquid phases. They are analysed as before in terms of the 3-step model, and it will be shown that this yields an optical density of states that differs considerably from the free electron picture.

6.2. Lead

6.2.1. Experimental

Lead was found to be a comparatively easy material for this experiment. It has a low melting point ($366^{o}C$), is ductile and is easy to pour. Lead is not highly reactive in the liquid, enabling the use of molybdenum specimen tables and quartz crucibles. Some trouble was experienced with quartz crucibles breaking due to thermal shock, and in one later experiment an alumina crucible was used. The results presented here are from three separate experiments.

6.2.2. Yield

Figure 6.1. shows the quantum yield for lead in both the solid and liquid states. The liquid yield has three major features - sharp peaks at 5.9 and 7.9 eV, with a broad peak centered at 9.5 eV. On freezing, the peak at 9.5 eV largely disappears and the peak at 5.9 eV splits into two peaks - a sharp one at 6.4 eV and a weaker feature at 5.5 eV. The magnitude of the yield remains largely the same although it is much higher than that observed by Norris et al (1972) and in the

Photon Energy(eV)——▶

solid ⎫ present
liquid ⎭ work

evap. film from
Norris (unpub.)
Fig.6.1-Yield of solid & liquid Lead

later work of Wotherspoon (loc.cit.). However, Wotherspoon did

observe similar behaviour on freezing.

A Fowler plot (Figure 6.2.) gives a value for the work

function of 3.94 ± .03 eV for the solid and 3.99 ± .03 eV for

the liquid. This is in excellent agreement with the value of

3.95 eV obtained by Norris et al (1972). In the absence of

any suitable reflectivity data for liquid lead, both solid

and liquid yields were calculated using the results of Lemmonier

et al (1973) for evaporated films (Figure 6.2.).

6.2.3.   Liquid Lead

Figure 6.3. shows EDC's obtained for liquid lead for low

photon energies. Only one major feature is apparent – the peak

at -2.6 eV which is very strong. These EDC's are very similar to

those obtained by Norris et al (1972) for an evaporated film

except that the peak seen in that work, just below the Fermi edge,

does not appear. The structure seen appears to be constant

both in position and strength. The position of the major

feature differs from that observed by Wotherspoon (loc.cit.) who

placed it at -1.9 eV in the liquid.

6.2.4.   Solid Lead

There are two sets of EDC's for solid lead. As explained

in Chapter 5 the rate of freezing appears to affect the

crystallinity of the surface, which is very highly structured

(see Figure 6.4.) and, as may be seen from Figures 6.5. and 6.6,

the EDC's contain many features.

In the rapidly frozen solid the single major feature of

the liquid has split into three peaks. There is a major peak

Fig.6.6-Low energy EDCs for rapidly frozen Lead

centered at -3 eV, which appears to be fairly constant in strength.
This is flanked by two minor peaks, both of which vary in strength,
one   varying in position between -1.8 and -2 eV, appearing at
maximum strength at 10.2 eV photon energy, and one at -4.1 eV
appearing to increase in strength with photon energy.   There is
a suggestion that the major peak at -3 eV may be a doublet, as it
appears to be flat topped at higher photon energies, but this is
not resolved fully.

In the slowly frozen solid the same structure is apparent
but in a greatly weakened form.   The separate peaks are only
properly resolved at high photon energies, so that at lower
energies the merging of the peaks at -3.0 eV and -1.8 eV give the
appearance of a single peak centered at -2.6 eV as in the liquid.
The slowly frozen solid thus appears to be an intermediate step
in structure between the rapidly frozen solid and the liquid -
this is supported by the observation that the evaporated film
results of Norris et al (1972) are very liquid like.

6.2.5.   High Energy EDC's

Figures 6.7. and 6.8. show EDC's for solid and liquid
lead at 16.8 and 21.2 eV compared with those of Wotherspoon
(loc.cit.).   At these energies the separate peaks seen at low
energy in the solid are not resolved, and both liquid and solid
have a single feature at -2.6 eV.   The solid and liquid differ
quite strongly away from the Fermi edge, only one feature being
observed in the liquid - a peak at -7.5 eV.   In the solid two
features were observed - peaks at -5.5 and -11 eV, there being a
dip at -7.5 eV.   The results of Wotherspoon do not confirm
these features in the solid, although this may be due to freezing

film agree on the existence of a peak at −7.5 eV.

6.2.6. Optical Density of States

The 21.2 eV EDC for liquid lead was used, with the

background subtracted, as the starting point for an analysis, as

detailed previously. In Figure 6.9 it is compared with the XPS

result of Pollak (loc.cit.) which is in good agreement regarding

the peak at −2.6 eV.

Figure 6.10 shows the optical density of states obtained

from the analysis. This can be seen to differ considerably from

the free electron picture. Figure 6.11 shows the EDC's obtained

from this density of states compared with the experimental results.

Although the agreement of the yield at high energy is poor, it

may be seen that the agreement of both the structural strength

and position are good. The values for the absorption coefficient

were taken from Lemonnier et al (1973). The value of l_e obtained

from the analysis was 30Å. This is higher than the value of 10Å

obtained by Wotherspoon (loc.cit.) but is not inconsistent with

the work of Brundle (1974).

6.2.7. Discussion

As in the case of the previous two metals, the liquid

specimen shows behaviour characteristic of non−direct transitions,

whilst the solid behaviour is characteristic of direct transitions.

Again, as previously, the structure observed appears to be

invariant over a wide energy range indicating that the effects of

matrix elements are small.

Energy of initial state (eV)
Fig.6.10-Final optical density of states for liquid Lead
Fig.6.11-Comparison of calculated & experimental EDCs for liquid lead

The band structure for lead shows clearly separated p
and s bands and although the photon energies are too low in
this experiment for the s band to be clearly defined, due to
the large scattered peak on the high energy EDC's, the p band
is fully covered and the features seen in the optical density
of states may be identified with features in this band.
Figure 6.10 shows the final optical density of states compared
with the band structure of McFeely et al (loc.cit.) for the
spin orbit split situation. The dip in the ODOS at -3.8 eV
may be seen to correspond well with the bottom of the p band,
whilst the broad peak centered at -2.2 eV corresponds with the
major   peak in the band. The peak at the Fermi edge may
be associated with the minor peak in the p band. The onset of
the s band is masked by the effects of scattered electrons.
The relative heights of the peaks at -2.2 eV and at the Fermi
edge agree with the results of Ley et al (loc.cit.) for XPS, who
interpret the well defined dip between them (associated with a
dip in the p band at -1 eV) as being indicative of the effects
of spin orbit splitting, since theory indicates that this dip
would not be well resolved in a non spin orbit split case.

6.3.   TIN

6.3.1.   Experimental

Tin was also an easy metal to handle experimentally.
It has a low melting point $(252^{o}C)$ and may be contained in the
same way as lead. The results given here are from three
separate experiments, some of which have been reported earlier
(Norris et al 1972).

6.3.2.   Yield of Tin

Figure 6.12 shows the quantum yield of solid and liquid tin. There are several peaks, the major one being at 6.2 eV and notably stronger in the solid than in the liquid. There is a common peak at 7.7 eV. In the solid there is a peak at 9 eV followed by a dip at 9.4 eV and another peak at 11 eV. In the liquid the first peak is broader and occurs at 9.5 eV with the dip at 10.3 eV.

At lower energies, solid and liquid yields are identical. A Fowler plot (Figure 6.13) gives a work function of 4.27 ± .02 eV. This is in reasonable agreement with the value of Goetz (1929) (4.21 eV) but does not agree with the value obtained by Stevenson (1968) of 4.05 eV. In the absence of data on the reflectivity of liquid tin, both solid and liquid yields were arrived at using the data of Lemmonier et al (1967) for an evaporated film (Figure 6.13).

6.3.3.   Liquid Tin

Figure 6.14 shows the EDC's for liquid tin at low energy. As previously reported there are two main features. However, later work with improved resolution and signal to noise ratio indicates a slightly different position of these features — peaks occurring at -1.2 eV and -2.6 eV instead of -1.0 and 2.4 as given earlier. There is also a suggestion in an EDC, taken at a higher energy (11.2 eV) than used previously, that the peak at -2.6 may be an unresolved doublet since, at this energy, the peak is very broad and shows signs of splitting. The structure in the EDC's is consistent in position and strength for all photon energies used.

solid
---- liquid

Fig.6.12 -Yield of solid & liquid Tin
Fig.6.13-Reflectivity & Fowler plot for solid &
liquid Tin
Fig.6.14-Low energy EDCs for liquid Tin

6.3.4.   Solid Tin

Figure 6.15 shows a series of EDC's for rapidly frozen tin. With this material, attempts to produce a slowly frozen surface resulted in a very large slow electron peak indicative of contamination of the surface. There did not appear to be much small scale surface structure in the samples as seen in lead (see Figure 6.16), but only large scale deformations. This is borne out by the fact that the feature at -4.1 eV observed by Castelijns et al (1977) on a roughened film, and associated by them with surface states, is not observed.

The EDC's for solid tin appear fairly similar to those for the liquid. There are two major features which are both considerably stronger than in the liquid. One is located at -1.1 eV at low photon energies and moving to -1.5 at higher energies, the strength of the peak also varying. The other feature occurs at -3.2 eV in the 10.2 eV EDC, moving towards the Fermi edge and becoming weaker as the photon energy is reduced. The behaviour of this second peak is in agreement with the observations of Castelijns et al (loc.cit.) - however, they did not observe any movement of the peak closer to the Fermi edge, and this may be associated with the bulk nature of the sample.

6.3.5.   High Energy EDC's

As mentioned in 6.3.4., problems were encountered with contamination of the surface on freezing the tin. This problem was encountered even more strongly with the high energy sample, and useful EDC's could not be obtained for the solid. Also, neon was not available at the time of this experiment so that
Fig.6.15-Low energy EDC's for solid Tin
Fig.6.16-Surface of frozen Tin

EDC's could only be taken at 21.2 eV. Figure 6.17 shows an

EDC for liquid tin at 21.2 eV. This differs considerably from

that originally reported, but the original published results are

now believed to have been in error due to problems with the

detection system. The EDC shows the feature at -2.6 eV seen

in the low energy spectra, and there is also a broad peak

centered at -8 eV.

6.3.6.   Optical Density of States

The 21.2 eV EDC was used, with the background subtracted,

as the starting point for the analysis, and Figure 6.18 shows

this compared with Pollak's XPS result. The agreement near

the Fermi edge is good, although the structure seen by Pollak

at -6 eV is not apparent. Figure 6.19 shows the final optical

density of states obtained and, as with previous materials, this

differs considerably from the free electron picture. Figure

6.20 shows the predicted EDC's compared with the experimental

results. The agreement of the structure is good, although

again the yield is not in agreement at the higher energies.

The values used for the absorption coefficient were

taken from Lemmonier et al (1967). The value of l_e gained from

the analysis was $50\overset{o}{A}$. This is rather high and suggests that there

may be some other factor affecting the yield in this case.

6.3.7.   Discussion

As in the previous cases the structure seen in the

liquid EDC's is constant in position and strength over a wide

range of photon energies, suggesting that the effects of matrix

Fig. 6.20-Comparison of calculated & experimental EDCs for liquid tin

elements are not important. Unfortunately the photon energies

used are not great enough for the 5s band of tin to be fully

examined, although the peak at −7 eV in the 21.2 eV result

corresponds well with the onset of this band. The main dip

observed in the optical density of states corresponds well with

the bottom of the p band at −4.5 eV.

There is no density of states available for liquid

tin. However, Van Attekum (1978) has produced a density of

states for the solid. A smoothed version of this is shown

in Figure 6.19. There is strong structure in this density of

states, particularly in the presence of a peak at −5.3 eV.

Although this agrees well with the position of the lower

maximum in the ODOS this may be fortuitous as there are effects

due to scattered electrons. However, the agreement in the

structure in the p band close to the Fermi edge, particularly

in the presence of a strong peak at −1.5 eV, is good.

CHAPTER 7:—   MERCURY AND MERCURY ALLOYS

7.1.   Introduction

Mercury $(6s^2)$ is a divalent metal of Group IIA and has

a melting point of $-39^\circ C$. It is rhombohedral in the solid

phase. The electronic structure of mercury has been of

considerable interest for some time, since it was found that its

electronic properties, notably the resistivity and thermopower,

differ considerably from those of other metals. In order to

explain this, Mott (1966) suggested the existence of a strong

dip in the density of states near to the Fermi edge (a 'pseudogap').

However later work by Evans et al (1969) and Evans (1970),

succeeded in explaining the metal's properties in terms of a

new pseudopotential, without recourse to the idea of a pseudogap.

Still more recent calculations by Chan and Ballentine (1971)

and Ichikawa (1972) have given a density of states with a much

weaker dip near the Fermi level than that originally proposed

by Mott.

Since photoelectron spectroscopy may provide some evidence

as to the nature of the density of states, mercury is a

particularly attractive subject for this study. Mercury is an

easy metal to alloy so that, besides the possibility of directly

perceiving the dip near the Fermi edge, it may also be possible

to observe the effects of alloying on this dip. The predictions

of Mott indicate that if mercury is alloyed with indium, the dip

should be gradually filled in as the concentration of indium is

increased. If, however, it is alloyed with an alkali metal

such as sodium, it should be possible to observe the opposite

effect.

Finally, mercury also has a 5d band close enough to the
Fermi edge to be seen at the higher photon energies, and the
effect of alloying on this may be examined.

7.2.   Mercury

7.2.1.   Experimental

Experimentally, mercury presents a problem not encountered
with the other materials in this work.   Since the vapour pressure
at room temperature is $\simeq 2 \times 10^{-4}$ Torr, a mercury diffusion pump
must be used.   It also means that the sample cannot be baked in
the chamber since it would then evaporate totally.   The technique
adopted for the experiment was as follows.   The chamber was
assembled with a clean molybdenum table and quartz crucible,
but with no mercury in the crucible.   The system was baked and
pumped down to $< 10^{-10}$ torr and the table outgassed.   The system
was then brought up to atmospheric pressure by the admission of
dry nitrogen, the crucible filled as quickly as possible and the
system pumped down again — a pressure of $\simeq 10^{-6}$ torr being
attainable due to the small surface area of mercury exposed.
After a further outgas of the specimen table, the mercury was
then poured.   A system for distillation of the mercury into the
chamber was tried but this was not satisfactory as it took too
long and the sample was usually contaminated by the end of the
process.   Specimen loss due to evaporation did not prove to be a
problem, approximately half of the specimen being lost in 24 hours.
The use of a mercury pump had the additional advantage that, by
violent movements of the table, the old specimen could be shaken
off and a fresh sample poured, allowing more than one sample to
be examined on each run without affecting the pumping system.

Obviously, since there is such a high pressure of mercury

in the chamber, it is not possible to deposit a clean gold film

during the experiment. It was therefore necessary to conduct

a separate experiment, using the sodium salicyclate phosphor

mentioned in Chapter 4 as an intermediate standard, to measure

the yield. Unfortunately the results given here do not

represent a complete picture as the failure of the mercury pump,

mentioned in Chapter 4, caused the experimental programme to

be curtailed. The ambient vacuum during the experiment as

measured by mass spectrometer was $= 2 \times 10^{-5}$ torr of mercury

with traces of N_2, H_2O, O_2 and CO_2 totalling 4×10^{-9} torr.

In this chapter UPS results are presented for liquid

mercury and three mercury alloys $(Hg_{.50}-In_{.50}, Hg_{.75}-In_{.25}, Hg_{.96}-Na_{.04})$.

These are analysed in terms of the 3-step model, and it is shown

that they are consistent with the Mott pseudogap concept.

7.2.2. Yield of Mercury

Figure 7.1. shows the quantum yield of mercury. It

may be seen that this is characterised by several strong peaks –

at 6.7 eV, 8.8 eV, 9.9 sV and 11 eV. These peaks are constant

in position but not in strength, a repeat of the yield measurement

one hour after the initial measurement (which was taken just after

pouring) showing a considerable change. If this result is

compared with the electron impact spectrum of mercury vapour

(Skerbele et al 1969) or excitation potential values (Moore 1949)

it will be seen that there is extremely good correspondence in

the position of the peaks both with peaks in the electron impact

spectrum and with known excitation potentials, namely 6 P, 7 P,

9 P and 6p ^3P. Since the lowest ionization potential for

mercury vapour is 13.4 eV, there obviously cannot be photoemission

Fig.7.1-Yield of liquid Mercury

taking place from the vapour above the surface. It seems

likely, however, that the mercury atoms just above the surface

are being excited into a metastable state. These then de-excite,

and this results in the formation of photoelectrons in the bulk

closer to the surface than would normally accur, with a

consequently increased escape possibility (see Figure 7.2.).

This is borne out by the following experimental observations.

Firstly, the EDC's did not display the time dependence seen in

the yield and secondly, contamination of the sample caused the

structure to 'wash out' as expected from previous experiments

on other metals, whilst emission from the vapour should not be

sensitive to this.

The change in strength of the peaks may well be due to

a change in the amount of vapour present above the specimen,

possibly caused by the rate of evaporation reaching equilibrium

with the rate of pumping. Mild contamination did not appear to

particularly affect the system pressure — probably the high loss

rate of evaporation inhibits the formation of a surface 'skin'.

The reflection data used for calculation of the yield

was from Wilson and Rice (1966).

7.2.3. Liquid Mercury

Figure 7.3. shows EDC's for liquid mercury at room

temperature. It may be seen that there is a strong feature at

-2.3 eV, and a strong negative slope to the Fermi edge. This

strong negative slope is in direct contrast to the predictions

of Chan and Ballentine (loc.cit.), Ichikawa (loc.cit.) and Evans

(loc.cit.) which indicate a density of states sharply rising

towards the Fermi edge. The position agrees well with the

density of states of Kuroha et al (1977).

metastable state

Atoms then
de-excite

Mercury

Specimen table
Fig.7.2 Enhancement of mercury yield
Fig.7.3-Low energy EDCs from liquid Mercury

The feature at −2.3 eV is constant in strength and position. This is close in energy to the point where the first conduction band touches the Brillouin zone face in solid mercury as calculated by Dishman and Rayne (1968) at −2.4 eV and Keeton and Loucks(1966) at −2.7 eV,and may well be due to persistence of some aspects of the solid state band structure on melting. In particular it suggests that the structure in the EDC close to E_F is due to a region of low density of states associated with the overlap of the first and second conduction bands.

Figure 7.4 shows an EDC for mercury at $h V = 6$ eV in comparison with one obtained by Cotti et al (1973). It is possible to discern a slight negative slope approaching the Fermi edge, but the feature seen by Cotti et al (loc.cit.) at −1 eV is not resolved.

7.2.4.   Solid Mercury

An attempt was made to obtain EDC's from solid mercury using the 'cold table' system of Figure 7.5. However, whilst it proved possible to freeze mercury in this way, it was found that the high vapour pressure of mercury present in the system resulted in the condensation of mercury droplets onto the electrical contacts, shorting them out. This could possibly be avoided by using the distillation system shown in Figure 7.6. instead of the crucible system. By pouring from the capilliary syphon system onto an already cold table, the evaporation of mercury into the system may be kept to a minimum. Additional benefits would be both the ability to bake the system with the mercury present in the still and also to thoroughly outgas the mercury by distillation.

7.2.5.   High Energy EDC's

Figure 7.7 shows EDC's for liquid mercury at 16.8 and 21.2 eV. The two strong d band peaks, due to transitions from the occupied spin orbit split $5d_{5/2}$ and $5d_{3/2}$ core levels, at -7.6 eV and -9.8 eV are clearly defined. This observed spin orbit splitting of 2.2 eV compares with the value of 2.3 eV as deduced from the band structure of Keeton and Loucks (loc.cit.) and with the value of 1.87 eV obtained from atomic term tables (Moore 1958).

The small feature at -2.3 eV is again seen, as is the negative slope to the Fermi edge. There is also a feature at -5.5 eV in the 21.2 eV EDC which is almost certainly due to transitions from the upper d levels incited by the satellite β line in the gas discharge at 23.1 eV. There is a similar feature at -4.5 eV in the 16.8 eV EDC due to the β line in neon at 19.7 eV.

Mott has suggested that the ratio of the density of states at the Fermi level to the free electron value (the g factor) is = 0.7. This agrees well with the ratio of the height of the -2.3 eV feature to the height of the edge in the 21.2 eV EDC (0.66) where the effects of the 'escape profile' and the secondary background are low.

Figure 7.8 shows the effect of air contamination on mercury. This results in the formation of features at -1.9 and -3 eV and, as the contamination becomes very heavy, the d band peaks move away from the Fermi edge (exposure is given in Figure 7.8 in Langmuirs). This shows that the structure observed at -2.3 eV is not due to contamination or to contributions from the vapour.

7.2.6. Optical Density of States

In view of the effects due to the satellite lines in the high energy EDC's, the 10.2 eV EDC was used as a starting point for the analysis. Using the procedure detailed earlier a final optical density of states was obtained which is shown in Figure 7.9. compared with a free electron density of states. The strong negative slope to the Fermi edge and the strong feature at -2.3 eV are immediately apparent. The values used for the absorption coefficient were taken from the optical data of Wilson and Rice (loc.cit.). The analysis yielded a value of l_e of $10\text{\AA}$. Figure 7.10. shows the calculated EDC's compared with the experimental results. The structural agreement is good, but the agreement of the yields is fairly poor. However, this may be due to the contribution from the large scattered peak.

7.2.7. Discussion

As with the metals previously examined, the structure observed in the density of states is constant both in position and strength relative to the Fermi edge, indicating that the effects due to matrix elements are small. The most noticeable feature in the optical density of states is the strong negative slope below the Fermi edge which Mott (loc.cit.) attributes to the overlap of the first and second conduction bands. Whilst several workers have calculated densities of states for mercury, and that of Kuroha et al (loc.cit.) agrees well in the position of the feature at -2.3 eV, all indicate that the slope below the Fermi edge is positive. Figure 7.10. shows the comparison between the Kuroha density of states and the final optical

density of states. The results obtained in this work show better agreement with the original work of Mott than with that of later workers.

7.3. Mercury Alloys

7.3.1. Experimental

Experimentally, mercury alloys presented no more problems than pure mercury. The only alterations to the technique consisted of filtering the alloys through glass wool to remove oxide film and, in the case of mercury-sodium alloy, preparation under argon as the alloying is highly exothermic. Due to the evaporation of mercury during the course of the experiment there is some change in the composition of the alloy, but experiments on the rate of loss of pure mercury indicate this should be less than 5% for $Hg_{.50}-In_{.50}$ and $2\frac{1}{2}\%$ for $Hg_{.75}-In_{.25}$ over a period of 3-4 hours, which is long enough for the experiment.

7.3.2. Yield of Mercury - Indium Alloys

Figure 7.11 shows the yield of two mercury-indium alloys (taken shortly after pouring) compared with those of pure mercury and pure liquid indium. Reflectivity data is taken here from Siskind et al (1972), the values for 25at.% indium being extrapolated from their results for 20 and 30at.% indium.

As expected, the peaks due to the mercury vapour appear in both yields though it is noticeable that there is a change in the structure between 9 and 10.5 eV, strongest in the 50% indium yield, consistent with the presence of a corresponding peak in the yield of pure indium. No other changes are

YIELD OF MERCURY-INDIUM ALLOY

–·– Mercury$_{75}$- Indium$_{25}$

——— Mercury$_{50}$- Indium$_{50}$

– – – Pure Mercury

········· Pure Liquid Indium

Y(ω) (Electrons/absorbed photon) ⟶

Photon Energy (eV) ⟶
Fig.7.11-Yield of Mercury-Indium alloys

observed, except an overall increase in the yield, which is probably due to the higher reactivity of the indium resulting in a more oxidised surface. Figure 7.12 shows a Fowler plot for $Hg_{.75}-In_{.25}$. This gives a value of 4.39 ± 0.03 eV for the work function. Since the value obtained for liquid indium was 3.94 eV and the work function of pure mercury is generally taken as 4.5 eV (Riviere 1969) this result is not unreasonable. Unfortunately similar data for Hg and $Hg_{.50}-In_{.50}$ is not available.

7.3.3. Low Energy EDC's - Mercury-Indium

Figures 7.13 and 7.14 show low energy EDC's from two Hg - In alloys. In both alloys the slope approaching the Fermi edge is now positive - slightly so in the 25% alloy, more strongly so in the 50% alloy - and this is consistent with the filling of states near to the edge as predicted by Mott (loc.cit). The feature seen in pure mercury at -2.3 eV is not now observed in either alloy. Although the scattered peak in the 50% alloy is very large and could 'wash out' this feature, the scattered peak in the 25% alloy is not excessive, and this suggests that the peak is either greatly weakened or has been shifted in energy away from the Fermi edge.

Although the bulk composition of the alloy is known, there remains the question of whether there may be surface enrichment. A theory of this effect has been presented by Williams and Nason (1974) based on a pairwise bonding or quasi-chemical approach for solid binary alloys. Results for liquid Ag-Cu alloy (Norris et al 1976) have shown reasonable agreement with this, but it is not clear if in this present case, where
Fig.7.12-Reflectivity & Fowler plot for Mercury-Indium alloys
Fig.7.13 Low energy EDCs from Mercury.50-Indium.50.
Fig. 7.14 - Low energy EDCs from Mercury₇₅ Indium₂₅

there is a considerable loss of material from the surface and
the technique is probing deeper than the surface layer, the
theory is applicable.   A rough estimate of the alloy
concentration, based on the relative slope approaching the Fermi
edge for the different alloys and components, gives a result in
good agreement with the known bulk concentration.

7.3.4.   High Energy EDC's

Figure 7.15 shows EDC's for $Hg_{.50}-In_{.50}$ alloy at 21.2 and
16.8 eV.   It may be seen that the structure near the Fermi edge
is consistent with the low energy EDC's and that a weak feature
is now observed at about -2.6 eV (although, as with the weak
features in aluminium, precise location is difficult).   This
again is consistent with the predictions of Mott (loc.cit.).

The d-band peaks are again observed, but shifted both
in position and in width.   Figure 7.16 summarises the binding
energies relative to the Fermi level and the corrected widths
for Hg and $Hg_{.50}-In_{.50}$.

7.3.5.   Mercury-Sodium Alloy

As stated earlier, mercury-sodium alloy is difficult
to prepare, due to the very high reactivity of the sodium.
Because of this the surface oxidises readily and this results
in a large scattered peak in the EDC's.   Due to this problem
it was possible to obtain a useable EDC at only one photon
energy - 7.7 eV where the lamp output is greatest.

Figure 7.17 shows the EDC thus obtained for $Hg_{.96}-Na_{.04}$
alloy.   It may be seen that there is a strong negative slope
to the Fermi edge and that the feature at -2.3 eV has broadened

and is now centered at $=$ -1.3 eV. This again is in accord
with the predictions of Mott (loc.cit.), who suggested that on
alloying with an alkali metal the minimum in $N(E)$ would be
deepened and there would be a shift of the Fermi limit towards
higher energies.

7.3.6. Discussion

Figure 7.18 shows the effect of alloying on the slope
to the Fermi edge for pure mercury and three mercury alloys at
low photon energies. The alteration of this slope and the
movement of the feature which occurs at -2.3 eV in pure mercury
is consistent with the supposition by Mott of the existence of
a pseudogap in mercury, and with his predictions of the effects
of alloying.

In the high energy EDC's the d-band peaks observed in
pure mercury are observed to alter both in position and in
width. This difference in width reflects the greater d-d
overlap for the upper state. On alloying, the overlap of the
d-wave functions is reduced and the lines narrow. The alteration
of the peaks may be explained in fairly simplistic terms. The
binding energies reflect changes in the environment of the atoms
and there will be local Fermi level differences.
Since mercury is more electronegative than indium, electrons will
be attracted to the mercury from the upper part of the indium
valence band, causing a shift in the position of the band
structure.

CHAPTER 8:—   SUMMARY AND CONCLUSIONS

8.1.   Summary of Yields and Work Function

In Table 8.1 the work function of the elements studied are summarised and compared with the results of other workers. It may be seen that there is very little change observed between the solid and liquid phases, and the change that is observed lies well within the limits of error of the measurement. This is not unexpected considering that very little change is observed in the EDC's on melting. Except in the case of aluminium, the values obtained are in good agreement with those of earlier workers, the differences observed again being well within the limits of experimental error. The value for lead is also in good agreement with the theoretical predictions of Lang and Kohn (1971), which give a value of between 3.80 and 3.95 eV depending on the crystal face. The discrepancy in the case of aluminium is not surprising since the strong oxygen affinity of this metal makes clean surfaces very difficult to prepare and early values of the work function differ considerably. Also, the value quoted here from Riviere (1969) was obtained using a contact potential difference method which frequently gives values that are not in accord with photoelectron measurements.

A systematic movement of the value of the work function with valence is observed, the work function increasing with increasing valence, e.g. the value of 4.02 eV for aluminium lies between that of 3.66 eV for magnesium and 5.4 eV for silicon. In group 5 the progression, ignoring the transition elements, is:—

Element	Work function (eV)		Previous solid results
	liquid	solid	
Aluminium	4·02±·02	4·02±·02	4·19[*]
Indium	3·94±·07	4·06±·10	4·08[×]
Tin	4·27±·02	4·27±·02	4·28[*]
Lead	3·99±·03	3·94±·03	3·94[•]

and in group 6:-

Cs	Ba	Tl	Pb	Bi
1.96	2.48	3.84	3.94	4.25

The other values here are taken from Wotherspoon (1978), Riviere (loc.cit.)and the CRC Handbook (1973). This variation of the work function is not inconsistent with the concept that the nucleus is imperfectly screened by the electrons. There is also a general reduction in work function moving from group $4 \rightarrow 5 \rightarrow 6$.

Table 8.2. shows a summary of the quantum yields, at 7.7 and 10.2 eV, of the materials studied. It may be seen that, as in the case of the work function, there is very little difference between the solid and liquid. Again this is not inconsistent with the comparatively small changes seen in the EDC's on melting. It has been shown in Chapter 3 that the effect of the change, on melting, of the electron-phonon mean free path on the yield should be comparatively small and this is borne out by these results. It is worth noting however that there appears to be a correlation between the change in yield on melting and the degree of change in the structure observed in the EDC's, although this is obviously difficult to quantify. The largest change of yield is observed in the melting of rapidly frozen indium, the smallest in the melting of aluminium. This is not inconsistent with the solid showing the most structured EDC's being the most crystalline in nature, and thus having a longer electron-phonon mean free path than solid frozen into a more amorphous state.

Element	Yield (Electrons/absorbed photon)				Calc. l_e at 8.6 eV above E_f (Å)
	$\hbar\omega = 7.7\,eV$		$\hbar\omega = 10.2\,eV$

8.2.   Summary of Optical Density of States.

Figures 8.3, 8.4, and 8.5 summarises the optical density

of states of the materials in this work and compares them with

the results of Wotherspoon (1978) for Ga, Tl and Bi.   What

is immediately noticeable is that none of the ODOS's are free

electron like.   In all cases clear, distinct and consistent

structure is seen in the ODOS's.   If the ODOS's are compared

with theoretical densities of states for both the liquid and

solid it may be seen that the predicted structure in the liquid

is always far weaker than that actually observed, whilst the

agreement between the predicted solid densities of states and

the ODOS's is good.   This is consistent with the idea that some

type of band-like structure is retained even after melting has

taken place.

Figure 8.3 shows the variation of the optical density

of states with valence through the elements Hg, Tl, Pb and Bi.

Movement of the main minimum (shown in the diagrams by ↓)

away from the Fermi level is apparent as the valence increases.

If the ODOS is compared with the solid state band structure,

it may be seen that the position of this minimum is consistent

with the bottom of the 6p band.   This behaviour may be inter-

preted in terms of the 6s band moving lower in energy with a

simultaneous filling of the 6p band.   If the ODOS for lead is

compared with the theoretical predictions of McFeeley et al (1977)

it may be seen that the relative heights of the ODOS at the

Hg: $6s^2$

Tl: $6s^2 6p^1$

Pb: $6s^2 6p^2$

Bi: $6s^2 6p^3$

N(E) (arb. units) →

Fig.8.4-Optical density of states for Al,Ga,In and Tl
Fig.8.5-Optical densities of states for In,Sn,Tl and Pb

Fermi edge and at the main maximum at -2.6 eV are consistent

with McFeely's predictions of the effects of spin orbit splitting.

In the ODOS for In and Sn it may be seen that again

there is a movement of the position of the main minimum with

increasing valence, consistent with the change in position of the

5p band, although here the 5s and 5p bands overlap to some extent.

The fact that the density of states does not go to zero between

the bands may indicate either a modification of the structure due

to melting or simply be an effect of the convolution of the

valence and conduction bands that has not been eliminated by the

method of derivation of the ODOS.

Figure 8.4 shows the ODOS for the trivalent elements

Al, Ga, In, Tl, i.e. moving from $3s^2 3p^1$ to $6s^2 6p^1$. As would

be expected, there are strong similarities in the ODOS notably

in the position of the main minimum at $\simeq -3$ eV, the bottom

of the p band. This dip becomes more dominant with increasing

z. This is consistent with band structure calculations which

indicate a marked overlap of the s and p bands in Al, which

lessens with increasing z until, in Tl, the bands are completely

separate. This is consistent with the screening of the nucleus

being less complete as the atom becomes heavier, resulting in

the s electrons being pulled away from the p band. Also as z

increases the agreement of the ODOS with the weak scattering

calculations becomes poorer.

8.3.   Effects of Matrix Elements.

In the preceeding chapters, in order to simplify the

interpretation of results using the 3-step process, the assumption

has been made that matrix elements are constant in the disordered

liquid system. In an ordered system the conservation of the

momentum vector $\underline{k}$ results in the variation of both the position

and the strength of the structure observed in the EDC's as a

function of photon energy. If however $\underline{k}$ is not conserved and

the assumption of constant matrix elements is justified, it would

be expected that the structure observed in the EDC's would remain

constant over a wide energy range. The results in this study

only cover a fairly narrow energy range (i.e. 4 - 21.2 eV) but

it may be seen that, for the liquid, the structure does remain

constant in both strength and position. Unfortunately this is

not really a wide enough energy range to state definitely that

the assumption is justified and there is a distinct lack of

high energy (XPS) results for liquid metals, (although Baer and

Myers (1977) have now published the results of XPS measurements

on liquid Bi). However the XPS results that have been used

for comparison in this study are for evaporated films and it may

be seen, by comparison of the low energy EDC's obtained in this

work with low energy EDC's for evaporated films (Norris et al

1974 and Wooten et al 1966) that these films show EDC's more

characteristic of the liquid than of the bulk solid. This

implies that the films are highly disordered (even if they are

not in a reproducible state of disorder).

Comparison of the XPS results for solid with the low

energy liquid results (see Figures 5.11, 5.9 and 6.19) show

good agreement between the two both in the position and strength

of structure within 7 eV of the Fermi edge. This strongly

implies that the contribution to the EDC's from the density of

states has remained unchanged over this energy range and hence

indicates that any effects from matrix elements are quite small.
Thus the assumption of constant matrix elements in this work does
appear to be reasonably well justified.

Williams and Norris (1975) have attempted to show
whether short range order is of importance to the optical matrix
elements by calculating, within the n.f.e. formalism, the
photoelectron spectra for a liquid using the quadratic response
formalism of Schaich and Ashcroft and avoiding most of the
simplifying approximations made in the 3-step process. Their
result, using this theory, shows reasonable agreement with
experiment in predicting the overall triangular shape of the
EDC despite the neglect of electron-electron scattering.
However the structure observed experimentally is not reproduced
at all. This implies that the weak scattering model is simply
not adequate to describe the electronic structure of simple
metals.

8.4. The N.F.E. Theory

As may be seen from the results obtained in Chapters
5, 6 and 7, the optical densities of states of the materials
examined show considerable variation from the free electron
picture although earlier measurements of optical and transport
properties (except in the cases of lead, thallium, bismuth and
mercury) were in good agreement with this theory.

Wotherspoon (1978) has examined this discrepancy
between the optical and UPS measurements for lead and bismuth
and offers a possible explanation. Most of the optical
measurements made have been at low energy and have involved

determination of ε_2, the imaginary part of the dielectric

control. The results for ε_2 are then normally considered in

terms of a Drude contribution described by the expression

$$\varepsilon_2^D = \frac{n\,e^2\tau}{m\varepsilon_o(1 + \omega^2\tau^2)} \qquad (8.1.)$$

and an interband contribution due to the optical excitation

of an electron from the filled valence band to a conduction

state. In the absence of strong peaks in the ε_2 results,

that may be associated with interband transitions, the results

are usually fitted to the Drude expression by adjusting the

value of n/m to find an effective carrier density. However

Smith (1967) has suggested that the fact that this adjustment

is necessary is itself indicative of a deviation from a free

electron situation.

Wotherspoon has used an optical density of states

similar to the one given in this work for lead to calculate ε_2

for liquid lead. From the expression:-

$$\varepsilon_2^B \; \alpha \; \int_{E_f}^{E_f+\hbar\omega} N_V(E) \; N_c(E - \hbar\omega)\,dE \qquad (8.2.)$$

for the interband contribution to ε_2 based on a non direct

transition model, he obtained good agreement with experimental

results at low photon energy. This implies strongly that the

lack of interband transitions seen in low energy optical work

cannot be taken as an indication of a free electron situation

and some high energy optical measurements are necessary to

settle this point.

Although the results of transport measurements have

been taken as evidence for the n.f.e. model, results for heavy

polyvalent metals such as lead show considerable discrepancies,

particularly in the value of the Hall coefficient,which indicates

that the weak scattering formalism simply is not adequate in

these cases.   With the other metals Al, In and Sn, although

the results for these fit the nearly free electron picture

reasonably well, it has been shown by Edwards (1962) that the

transport properties are not a sensitive indication of

variations in the density of states and this agreement cannot

be regarded as a necessary indication of a featureless parabolic

density of states curve.

8.5.   Further Work

Whilst good results were obtained for In, Al, Sn, Pb

and Hg, the failure of the mercury diffusion pump meant that a

full investigation of the mercury alloys could not be carried

out.   The results obtained before the failure indicate that there

is a need for a complete study of the mercury alloys if the

'pseudogap' controversy is to be resolved.

The apparatus itself has obvious room for improvement

both in the analyser and the light source.   As stated in Chapter

4, the retarding field type of analyser was chosen because it was

anticipated that there would be considerable trouble with

evaporation of the sample and consequent condensation in the

analyser.   However this did not occur and, since a higher

resolution would be most desirable, another type of analyser,

such as a cylindrical mirror analyser (C.M.A.), could be adopted —

certainly a higher signal/noise ratio could be obtained using counting electronics rather than the system used in this study. The ability to cover a wider photon energy range would also be most desirable. The comparatively narrow range used in this study meant that the effects of matrix elements had to be estimated from solid XPS results. There is a considerable need for high resolution XPS measurements of the liquid phase if a true comparison is to be obtained.

Finally there are further interesting materials that may be examined. Very little work has been done to date on liquid alloys and in particular there is little data on the liquid semiconductors, Ga-Sc, Tl-Te, Mg-Bi and Li-Bi, (see Enderby 1972). These alloys have very high vapour pressures ($\simeq 10^{-3}$ torr) but,with the use of specialised pumping systems using diffusion or high speed turbo-molecular pumps,the work should not be impossible. However because of the problems of surface enrichment, it would be necessary to add an Auger spectrometer to the system to obtain a measure of the surface composition. Again a C.M.A. spectrometer should be used as high sensitivity is necessary for this work.

8.6. Conclusions

This work, taken in conjunction with the later work of Wotherspoon (1978), represents the first systematic photoemission study of liquid metals under ultra clean conditions. Whilst other workers have examined isolated elements, it is only by means of a systematic study, enabling comparison of the elements in a series, that major overall effects can be discerned and generalisations made.

The work function, quantum yield and low energy
photoelectron spectra have been measured for Al, In, Sn and
Pb in the liquid and solid states and for mercury and some
mercury alloys.   Comparison of the solid phase data with
previous work and examination of the low energy scattered
peak in the photoelectron spectra have shown that the liquid
surfaces obtained were virtually free of contamination.   The
results obtained indicate that there is very little change in
the yield of Al, In, Sn or Pb on melting and this has been
shown to be not inconsistent with the reduction of the electron
phonon mean free path on melting.   The optical densities of
states which have been derived for these four metals are
inconsistent with the Ziman weak scattering formalism and agree
better with the solid state band structure, indicating that
elements of this structure may well persist on melting.   No
evidence for k conservation or for non-constant matrix elements
was observed in the liquid state.   In the case of mercury and
its alloys, it has been shown that their behaviour is consistent
with the original Mott prediction of a 'pseudogap' and does
not accord well with later theoretical work.

APPENDIX I: The Monte Carlo programme

This version of the programme is in Algol for the

Nottingham University 1906 computer.   A later version

in Fortran will be found in Wotherspoon (1978).

Program symbols

All units of energy are in 0.1eV measured with respect to the bottom of the valence band. The lengths are in Angstrom units.

E1   Valence band width.

E2   Photon energy.

E3   Workfunction.

E4   Energy at any given time.

E5   Energy given up at an electron-ion collision.

E6   Energy of secondary after the scattering event.

E9   Energy at which l_e is defined.

E10   Energy given up filling the valence hole in the Auger process.

E11   Energy of Auger process which is generated.

L1   Length of primary electron walk.

L2   Mean free path of the photoelectron at the particular final state energy.

L3   Electron-ion mean free path.

L4   Length of secondary walk.

L5 l_e corrected for the final state energy.

L6   Absorption coefficient.

L8   Length of Auger walk.

T1   Angle of travel, with respect to the surface normal, for the primary.

T2   Angle of travel, with respect to the surface normal, for the secondary.

T3   Angle of travel, with respect to the surface normal, for the Auger.

X1   Instantaneous distance of electron from the surface.

C3   Sum of generation depths of electrons which have escaped.

U1
          Variables used in the Simpson's Rule calculation.
U2

H1   The separation of energy points in the density of states.

Y1, Y2, Y3, Y4   Primary yield in four angular sections.

Y5, Y6, Y7, Y8   Secondary yield in four angular sections.

Y9, Y10, Y11, Y12   Auger yield in four angular sections.

N1   Total number of photons.

N2   Number of slots into which the density of states is split.

D1   Density of states below the Fermi level.

U   Density of states above the Fermi level.

APPENDIX II: The modified Krolikowski programme

Program symbols

All units of energy are 0.1eV and the lengths are in Angstroms.

N1   Workfunction.

N2   Photon energy.

A   Absorption coefficient.

IH   Valence band width.

NVAL   Number of valence electrons.

V   Valence density of states.

C   Conduction band density of states.

X   Electron-hole pair inelastic mean free path.

PL   Plasmon loss mean free path.

TL   Total inelastic mean free path.

T   Semi-classical threshold function.

PO1   The internal energy distribution of photoexcited electrons.

TF2   The effective threshold function.

SEE   Distribution function of secondary electrons.

D   External energy distribution of secondary electrons.

HL   Hole scattering length.

SHE   The hole distribution function.

GD   Plasmon loss distribution function.

DPLAS   The external energy distribution of plasmon loss electrons.

PS   The external energy distribution of primary electrons.

TER(I) The tertiary distribution function.

TER(N) The external tertiary energy distribution function.

SUM 7   The primary yield.

SUM 8   The secondary yield.

SUM 10   The Auger yield.

SUM 11   The plasmon loss yield.

SUM 12   The tertiary yield.

SUM 9   The total yield.

C2   The total external energy distribution function.

PO2   The total external scattered energy distribution function.

Photoemission Studies of some Liquid Simple Metals and Alloys

Donald Charles Rodway

Abstract

Measurements of the work function, quantum yield and low energy
$(6.0eV < h\nu < 21.2eV)$ photoelectron spectra are presented for the
simple metals In, Al, Pb, and Sn in the liquid and frozen solid
states, and for Hg and the mercury alloys $Hg_{.5}-In_{.5}$, $Hg_{.75}-In_{.25}$, $Hg_{.96}-Na_{.04}$
in the liquid states only.   The results obtained for the solid
simple metals are consistent with other published results.   The
results for the liquid are very similar to those for the solid and
are constant over a broad temperature range above the melting point.
A Monte Carlo simulation of the photoemission process, based on
the 3-step model of Berglund and Spicer, has been developed and used
to examine the effects of variation of the electron-phonon scattering
length on the quantum yield and the escape depth of the photoelectrons.
This programme has been used in conjunction with an analytical
programme, based on the work of Krolikowski, to derive optical density
of valence states functions and electron-electron scattering lengths
for the liquids.
In all cases the optical density of states functions show much
stronger structure than expected on the basis of a weak scattering
description of the liquid system and agree better with theoretical
predictions for the solid, indicating that some aspects of the solid
state band structure persist on melting.   No evidence for conservation
of the momentum vector $\underline{k}$ or for non-constant matrix elements is
observed.
In the case of mercury and the mercury alloys the results
obtained agree well with the 'pseudogap' concept proposed by Mott.
